Atrial ectopic beats usually cause no symptoms but can give the sensation of a missed beat or an abnormally strong beat. The ECG (Fig. 16.33) shows a premature but otherwise normal QRS complex; if visible, the preceding P wave has a different morphology because the atria activate from an abnormal site. In most cases these are of no consequence, although very frequent atrial ectopic beats may herald the onset of atrial fibrillation.

Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, with an overall prevalence of 0.5% in the adult population of the UK. The prevalence rises with age, affecting 1% of those aged 60–64 years, increasing to 9% of those aged over 80 years. It is associated with significant morbidity and a twofold increase in mortality. This is mainly because of its association with underlying heart disease but also because of its association with systemic embolism and stroke.

Pathogenesis

AF is a complex arrhythmia characterised by both abnormal automatic firing and the presence of multiple interacting re-entry circuits looping around the atria. Episodes of AF are initiated by rapid bursts of ectopic beats arising from conducting tissue in the pulmonary veins or from diseased atrial tissue. It becomes sustained because of re-entrant conduction within the atria or sometimes because of continuous ectopic firing (Fig. 16.36). Re-entry is more likely to occur in atria that are enlarged or in which conduction is slow, as is the case in many forms of heart disease. During episodes of AF, the atria beat rapidly but in an uncoordinated and ineffective manner. The ventricles are activated irregularly at a rate determined by conduction through the AV node. This produces the characteristic ‘irregularly irregular’ pulse. The ECG (Fig. 16.37) shows normal but irregular QRS complexes; there are no P waves but the baseline may show irregular fibrillation waves. Commonly, AF is classified as paroxysmal (intermittent episodes that self-terminate within 7 days), persistent

Atrial tachycardia

Atrial tachycardia may be a manifestation of increased atrial automaticity, sinoatrial disease or digoxin toxicity. It produces a narrow-complex tachycardia with abnormal P-wave morphology, sometimes associated with AV block if the atrial rate is rapid. It may respond to β-blockers, which reduce automaticity, or class I or III anti-arrhythmic drugs (see Box 16.30 below). The ventricular response in rapid atrial tachycardias may be controlled by AV node-blocking drugs. Catheter ablation (p. 484) can be used to target the ectopic site and should be offered as an alternative to anti-arrhythmic drugs in patients with recurrent atrial tachycardia.

Atrial flutter

Atrial flutter is characterised by a large (macro) re-entry circuit, usually within the right atrium encircling the tricuspid annulus. The atrial rate is approximately 300/min, and is usually associated with 2:1, 3:1 or 4:1 AV block (with corresponding heart rates of 150, 100 or 75/min). Rarely, in young patients, every flutter wave is conducted, producing a rate of 300/min and, potentially, haemodynamic compromise. The ECG shows saw-tooth flutter waves (Fig. 16.34). When there is regular 2:1 AV block, it may be difficult to identify flutter waves that are buried in QRS complexes and T waves. Atrial flutter should always be suspected when there is a narrow-complex tachycardia of 150/min. Carotid sinus pressure or intravenous adenosine may help to establish the diagnosis by temporarily increasing the degree of AV block and revealing flutter waves (Fig. 16.35).

Management

Medical management with digoxin, β-blockers or verapamil is often successful in controlling the ventricular rate (p. 479). In many cases, however, it may be preferable to try to restore sinus rhythm by direct current (DC) cardioversion. Following cardioversion, β-blockers or amiodarone can be used to prevent recurrent episodes of atrial flutter. Class Ic anti-arrhythmic drugs such as flecainide are contraindicated because there is a risk of slowing the flutter circuit, facilitating 1:1 AV nodal conduction and producing a paradoxical extreme tachycardia and haemodynamic compromise. Catheter ablation is a highly effective treatment, offering a greater than 90% chance of complete cure, and is the treatment of choice for patients with persistent symptoms. Anticoagulant management in patients with atrial flutter, including management around cardioversion, is identical to that of patients with atrial fibrillation (p. 471).
There is usually a fast ventricular rate, between 120 and 160/min, at the onset of atrial fibrillation. In chronic atrial fibrillation, the ventricular rate may be much slower, due to the effects of medication and AV nodal fatigue. Clinical features

Many forms of heart disease can present with AF (Box 16.21), particularly those that are associated with enlargement or dilatation of the atria. Alcohol excess, hyperthyroidism and chronic lung disease are also common causes of AF, although multiple predisposing factors may coexist, such as the combination of alcohol, hypertension and coronary artery disease. About 50% of all patients with paroxysmal AF and 20% of patients with persistent or permanent AF have structurally normal hearts; this is known as ‘lone atrial fibrillation’.

Paroxysmal atrial fibrillation

Occasional attacks of AF that are well tolerated do not necessarily require treatment. Beta-blockers are normally used as first-line therapy if symptoms are troublesome, since they reduce the ectopic firing that normally initiates the arrhythmia. They are particularly useful for treating patients with AF associated with coronary artery disease, hypertension and cardiac failure. Class Ic drugs (see Box 16.30), such as propafenone or flecainide, are also effective at preventing episodes but should not be given to patients with coronary artery disease or left ventricular dysfunction. Flecainide is seldom used alone, since it can precipitate atrial flutter, and is usually prescribed with a rate-limiting β-blocker. Class III drugs can also be used; amiodarone is the most effective agent for preventing AF but side-effects restrict its use to when other measures fail. Dronedarone is an effective alternative but is contraindicated in patients with heart failure or significant left ventricular impairment. Digoxin and verapamil are not effective for the prevention of AF but can help with rate control by slowing conduction through the AV node. Catheter ablation can be considered where anti-arrhythmic drug therapy is ineffective or causes side-effects. Ablation can disconnect the pulmonary veins from the LA electrically, preventing ectopic triggering of AF. In addition, lines of ablation block can be created.
within the atria to prevent re-entry. Ablation prevents AF in approximately 75% of patients with prior drug-resistant episodes, although a repeat procedure is sometimes required before this is achieved. Ablation for AF is an attractive treatment when drugs are ineffective or poorly tolerated but may be complicated by cardiac tamponade, stroke, phrenic nerve injury and, rarely, pulmonary vein stenosis.

Persistent atrial fibrillation

There are two options for treating persistent AF. One is to attempt to restore and maintain sinus rhythm and the second is to accept the presence of AF and to try to control the ventricular rate. With both options prophylaxis against thromboembolism is required on either a short-term or long-term basis.

Rhythm control An attempt to restore sinus rhythm is particularly appropriate if the arrhythmia causes troublesome symptoms and if there is a modifiable or treatable underlying cause. Electrical DC cardioversion (p. 482) or pharmacological cardioversion may be used. Cardioversion is initially successful in most patients but relapse is frequent (25–50% at 1 month and 70–90% at 1 year). Attempts to restore and maintain sinus rhythm are most successful if AF has been present for less than 3 months, the patient is young and there is no important structural heart disease.

Immediate cardioversion is appropriate if AF has been present for less than 48 hours. In stable patients with no history of structural heart disease, intravenous flecainide (2 mg/kg over 30 mins, maximum dose 150 mg) can be used for pharmacological cardioversion and will restore sinus rhythm in 75% of patients within 8 hours. In patients with structural or ischaemic heart disease, intravenous amiodarone can be given through a central venous catheter. Cardioversion is an alternative treatment and is often effective when drugs fail. If AF has been present for 48 hours or longer, or if there is doubt about its duration, DC cardioversion should be deferred until the patient has been established on effective oral anticoagulation for a minimum of 4 weeks and any underlying problems, such as hypertension or alcohol excess, have been corrected. Consideration should be given to prophylactic treatment with amiodarone to reduce the risk of recurrence. Catheter ablation is sometimes used to restore and maintain sinus rhythm in resistant cases but is a less effective treatment than for paroxysmal AF.

Rate control If sinus rhythm cannot be restored, treatment should be directed at maintaining an appropriate heart rate. Digoxin, β-blockers and rate-limiting calcium antagonists, such as verapamil or diltiazem (p. 479), reduce the ventricular rate by slowing AV conduction. This alone may produce a striking improvement in cardiac function, particularly in patients with mitral stenosis. Beta-blockers and rate-limiting calcium antagonists are more effective than digoxin at controlling the heart rate during exercise and have additional benefits in patients with hypertension or structural heart disease. Combination therapy with digoxin and a β-blocker can help with rate control but calcium channel antagonists should not be used with β-blockers because of the risk of bradycardia.

In exceptional cases, poorly controlled and symptomatic AF can be treated by implanting a permanent pacemaker and then deliberately inducing complete AV nodal block with catheter ablation. This is known as the ‘pace and ablate’ strategy.

Thromboprophylaxis Loss of atrial contraction and left atrial dilatation cause stasis of blood in the LA and may lead to thrombus formation in the left atrial appendage. This predisposes patients to stroke and other forms of systemic embolism.

### Atrial fibrillation in old age

- **Prevalence:** rises with age, reaching 9% in those over 80 years.
- **Symptoms:** sometimes asymptomatic but often accompanied by diastolic heart failure.
- **Hyperthyroidism:** atrial fibrillation may emerge as the dominant feature of otherwise silent or occult hyperthyroidism.
- **Cardioversion:** followed by high rates (~70% at 1 year) of recurrent atrial fibrillation.
- **Stroke:** atrial fibrillation is an important cause of cerebral embolism, found in 15% of all stroke patients and 2–8% of those with transient ischaemic attacks (TIAs).
- **Anticoagulation:** although the risk of thromboembolism rises, the hazards of anticoagulation also become greater with age because of increased comorbidity, particularly cognitive impairment and falls.
- **Target INR:** if anticoagulation is recommended in those over 75 years, care should be taken to maintain an INR below 3.0 because of the increased risk of intracranial haemorrhage.
- **Directly acting oral anticoagulants:** alternatives to warfarin. No blood monitoring is required, there are fewer drug interactions, and fixed dosing may aid adherence.

Patients undergoing cardioversion to restore sinus rhythm require temporary anticoagulation to reduce the risk of systemic embolus. This can be achieved with warfarin, aiming for an international normalised ratio (INR) target of 2.0–3.0. Increasingly, direct-acting oral anticoagulant drugs (see below) are used as an alternative. Anticoagulation should be started for at least 4 weeks before cardioversion and should be maintained for at least 3 months following successful cardioversion.

In patients with chronic AF, the annual risk of stroke is influenced by many factors and a decision has to be made in which the risk of stroke is balanced against the risk of bleeding with anticoagulation. Patients with AF secondary to mitral valve disease should always be anticoagulated because the risk is so high. In other patients, clinical scoring systems can be used to assess the risk of stroke and bleeding. The risk of stroke is usually assessed by the CHA2DS2-VASc score (Box 16.23), whereas the HAS-BLED score can be used to estimate the bleeding risk (Box 16.24). Patients with a HAS-BLED score of 3 or more points may require more careful monitoring if anticoagulated.

In patients with intermittent AF, stroke risk is similar to that in patients with persistent AF when adjusted for CHA2DS2-VASc score. The risk of embolism is only weakly related to the frequency and duration of AF episodes, so stroke prevention guidelines do not distinguish between those with paroxysmal, persistent and permanent AF.

Several agents can be used to reduce stroke risk in AF. Warfarin therapy adjusted to a target INR of 2.0–3.0 reduces the risk of stroke by about two-thirds at the cost of an annual risk of bleeding of 1–1.5% and is indicated for patients with a CHA2DS2-VASc score of 2 or more, unless there are coexisting clinical risk factors that increase the risk of bleeding. These include peptic ulcer, uncontrolled hypertension, alcohol misuse, frequent falls, poor adherence and the use of other drugs that might interact with warfarin. If bleeding does occur in warfarin-treated patients, anticoagulation can be reversed by administering vitamin K or clotting factors.

The factor Xa inhibitors rivaroxaban, apixaban and edoxaban, and the direct thrombin inhibitor dabigatran (collectively referred
Supraventricular tachycardia

The term supraventricular tachycardia (SVT) describes the occurrence of a group of regular tachycardias that have a similar appearance on ECG. These are usually narrow-complex tachycardias and are characterised by a re-entry circuit or automatic focus involving the atria. The three principal types are atrioventricular nodal re-entrant tachycardia (AVNRT), atrioventricular re-entrant tachycardia (AVRT) and atrial tachycardia. The term SVT is technically incorrect as, in many cases, the ventricles also form part of the re-entry circuit.

Atrioventricular nodal re-entrant tachycardia

AVNRT is a type of SVT caused by re-entry in a circuit involving the AV node and its two right atrial input pathways: a superior ‘fast’ pathway and an inferior ‘slow’ pathway (see Fig. 16.39A below). This produces a regular tachycardia with a rate of 120–240/min. It tends to occur in the absence of structural heart disease and episodes may last from a few seconds to many hours. The patient is usually aware of a rapid, very forceful, regular heart beat and may experience chest discomfort, lightheadedness or breathlessness. Polypuria, mainly due to the release of ANP, is sometimes a feature. The ECG (Fig. 16.38) usually shows a tachycardia with normal QRS complexes but occasionally there may be rate-dependent bundle branch block.

Management

Treatment is not always necessary. However, an acute episode may be terminated by carotid sinus pressure or by the Valsalva manoeuvre. Adenosine (3–12 mg rapidly IV in incremental doses until tachycardia stops) or verapamil (5 mg IV over 1 min) will restore sinus rhythm in most cases. Intravenous β-blocker or flecainide can also be used. In rare cases, when there is severe haemodynamic compromise, the tachycardia should be terminated by DC cardioversion (p. 482).

In patients with recurrent SVT, catheter ablation (p. 484) is the most effective therapy and will permanently prevent SVT in more than 90% of cases. Alternatively, prophylaxis with oral β-blocker, verapamil or flecainide may be used but commits predominantly young patients to long-term drug therapy and can create difficulty in female patients, as these drugs are normally avoided during pregnancy.

Atrioventricular re-entrant tachycardia

In this condition there is an abnormal band of conducting tissue that connects the atria and ventricles. This so-called accessory pathway comprises rapidly conducting fibres that resemble Purkinje tissue, in that they conduct very rapidly and are rich in sodium channels. In about 50% of cases, this pathway conducts only in the retrograde direction (from ventricles to atria) and thus does not alter the appearance of the ECG in sinus rhythm. This is known as a concealed accessory pathway. In the rest, the pathway also conducts in an antegrade direction (from atria to ventricles), so AV conduction in sinus rhythm is mediated via both the AV node and the accessory pathway, distorting the QRS complex. Premature ventricular activation via the pathway shortens the PR interval and produces a ‘slurred’ initial deflection
Ventricular premature beats (VPBs) are frequently found in healthy people and their prevalence increases with age. Ectopic beats in patients with otherwise normal hearts are more prominent at rest and disappear with exercise. Sometimes VPBs are a manifestation of subclinical coronary artery disease or cardiomyopathy but also may occur in patients with established heart disease following an MI. Most patients with VPBs are asymptomatic but some present with an irregular heart beat, missed beats or abnormally strong beats, due to increased cardiac output of the post-ectopic sinus beat. On examination the pulse is irregular, with weak or missed beats as a result of the fact that the stroke volume is low because left ventricular contraction occurs before filling is complete (Fig. 16.40). The ECG shows broad and bizarre complexes because the ventricles are activated sequentially rather than simultaneously. The complexes may be unifocal (identical beats arising from a single ectopic focus) or multifocal (varying morphology with multiple foci, Fig. 16.40). ‘Couplet’ and ‘triplet’ are the terms used to describe two or three successive ectopic beats. A run of alternating sinus and ventricular ectopic beats is known as ventricular ‘bigeminy’. The significance depends on the presence or absence of underlying heart disease.

Management

Treatment may not be necessary, unless the patient is highly symptomatic, in which case β-blockers or, in some situations,
Cardiac arrhythmias

• Catheter ablation can be used. There is no evidence that anti-arrhythmic therapy improves prognosis but the discovery of very frequent VPBs in a patient not known to have heart disease should prompt further investigations with echocardiography and an exercise ECG to screen for structural heart disease and ischaemic heart disease. It is common for VPBs to occur during the course of an acute MI. Persistent, frequent VPBs (over 10/hr) in patients who have survived the acute phase of MI indicate a poorer long-term outcome. In this situation, anti-arrhythmic drugs do not improve and may even worsen prognosis. The exception is β-blockers, which should be prescribed for other reasons (p. 500). Similarly, heart failure of any cause is associated with VPBs. While they indicate an adverse prognosis, this is not improved by anti-arrhythmic drugs. Effective treatment of the heart failure may suppress the ectopic beats. VPBs are also a feature of digoxin toxicity.

Ventricular ectopic beats

Ventricular tachycardia (VT) occurs most commonly in the settings of acute MI, chronic coronary artery disease and cardiomyopathy. It is associated with extensive ventricular disease, impaired left ventricular function and ventricular aneurysm. In these settings, VT may cause haemodynamic compromise or degenerate into ventricular fibrillation (p. 456). VT is caused by abnormal automaticity or triggered activity in ischaemic tissue, or by re-entry within scarred ventricular tissue. Patients may complain of palpitation or symptoms of low cardiac output, including dyspnoea, lightheadedness and syncope. The ECG shows tachycardia and broad, abnormal QRS complexes with a rate of more than 120/min (Fig. 16.41). It may be difficult to distinguish VT from SVT with bundle branch block or pre-excitation (WPW syndrome) on ECG but features in favour of VT are listed in Box 16.25. A 12-lead ECG (Fig. 16.42) or electrophysiology study (p. 454) may help establish the diagnosis. When there is doubt, it is safer to manage the problem as VT.

Management

Prompt action to restore sinus rhythm is required and should usually be followed by prophylactic therapy. Synchronised DC cardioversion is the treatment of choice if systolic BP is less than 90 mmHg. If the arrhythmia is well tolerated, intravenous amiodarone may be given as a bolus, followed by a continuous infusion (p. 481). Intravenous lidocaine can be used but may depress left ventricular function, causing hypotension or acute heart failure. Hypokalaemia, hypomagnesaemia, acidosis and hypoxia should be corrected if present.

Beta-blockers are effective at preventing VT by reducing ventricular automaticity. Amiodarone can be added if additional
control is needed. Class Ic anti-arrhythmic drugs should not be used for prevention of VT in patients with coronary artery disease or heart failure because they depress myocardial function and can increase the likelihood of a dangerous arrhythmia. In patients with poor left ventricular function or where VT is associated with haemodynamic compromise, the use of an implantable cardiac defibrillator is recommended (p. 483). Rarely, surgery with resection of a ventricular aneurysm or catheter ablation can be used to interrupt the arrhythmia focus or circuit in patients with VT associated with a myocardial infarct scar. The treatment of choice for VT occurring in a normal heart is catheter ablation, which often can be curative.

**Torsades de pointes**

This form of polymorphic VT is a complication of prolonged ventricular repolarisation (prolonged QT interval). The ECG shows rapid irregular complexes that seem to twist around the baseline as the mean QRS axis changes (Fig. 16.43). The arrhythmia is usually non-sustained and repetitive, but may degenerate into ventricular fibrillation. During periods of sinus rhythm, the ECG will usually show a prolonged QT interval (>0.44 sec in men, >0.46 sec in women when corrected to a heart rate of 60/min).

Some of the common causes are listed in Box 16.26. The arrhythmia is more common in women and is often triggered by a combination of factors, such as administration of QT-prolonging medications and hypokalaemia. The congenital long QT syndromes are a family of genetic disorders that are characterised by mutations in genes that code for cardiac sodium or potassium channels. Long QT syndrome subtypes have different triggers, which are important when counselling patients. Adrenergic stimulation through vigorous exercise is a common trigger in long QT type 1, and a sudden noise may trigger arrhythmias in long QT type 2. Arrhythmias are more common during sleep in type 3.

**Management**

Intravenous magnesium (8 mmol over 15 mins, then 72 mmol over 24 hrs) should be given in all cases. If this is ineffective,

---

**Fig. 16.42 Ventricular tachycardia: 12-lead ECG.** There are typically very broad QRS complexes and marked left axis deviation. There is also atrioventricular dissociation; some P waves are visible and others are buried in the QRS complexes (arrows).

**Fig. 16.43 Torsades de pointes.** A bradycardia with a long QT interval is followed by polymorphic ventricular tachycardia that is triggered by an R on T ectopic.
progressive lengthening of successive PR intervals, culminating in a dropped beat. The cycle then repeats itself. This is known as the Wenckebach phenomenon and is usually due to impaired conduction in the AV node itself. The phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults with high vagal tone.

In Mobitz type II second-degree AV block (Fig. 16.46), the PR interval of the conducted impulses remains constant but some P waves are not conducted. This is usually caused by disease of the His–Purkinje system and carries a risk of asystole.

In 2:1 AV block (Fig. 16.47), alternate P waves are conducted, so it is impossible to distinguish between Mobitz type I and type II block.

Third-degree atrioventricular block
In third-degree AV block, conduction fails completely and the atria and ventricles beat independently. This is known as AV dissociation, as shown in Fig. 16.48. Ventricular activity is maintained by an escape rhythm arising in the AV node or bundle of His (narrow QRS complexes) or the distal Purkinje tissues (broad QRS complexes). Distal escape rhythms tend to be slower and less reliable. Complete AV block (Box 16.27) produces a slow (25–50/min), regular pulse that does not vary with exercise, except in the case of congenital complete AV block. There is usually a compensatory increase in stroke volume, producing a large-volume pulse. Cannon waves may be visible in the neck and the intensity of the first heart sound varies due to the loss of AV synchrony.

Clinical features
The typical presentation is with recurrent syncope or ‘Stokes–Adams’ attacks. These episodes are characterised by sudden

Atrioventricular block
This usually occurs as the result of disease affecting the AV node. AV block can be intermittent, however, and may become evident only when the conducting tissue is stressed by a rapid atrial rate. Reflecting this fact, atrial tachyarrhythmias are often associated with AV block (see Fig. 16.37). Episodes of ventricular asystole may also complicate complete heart block or Mobitz type II second-degree AV block. Several types of AV block are recognised.

First-degree atrioventricular block
In this condition, AV conduction is delayed and so the PR interval is prolonged (>0.20 sec; Fig. 16.44). It rarely causes symptoms and does not usually require treatment.

Second-degree atrioventricular block
Here dropped beats occur because some impulses from the atria fail to conduct to the ventricles. Two subtypes are recognised. In Mobitz type I second-degree AV block (Fig. 16.45), there is progressive lengthening of successive PR intervals, culminating in a dropped beat. The cycle then repeats itself. This is known as the Wenckebach phenomenon and is usually due to impaired conduction in the AV node itself. The phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults with high vagal tone.

In Mobitz type II second-degree AV block (Fig. 16.46), the PR interval of the conducted impulses remains constant but some P waves are not conducted. This is usually caused by disease of the His–Purkinje system and carries a risk of asystole.

In 2:1 AV block (Fig. 16.47), alternate P waves are conducted, so it is impossible to distinguish between Mobitz type I and type II block.

Third-degree atrioventricular block
In third-degree AV block, conduction fails completely and the atria and ventricles beat independently. This is known as AV dissociation, as shown in Fig. 16.48. Ventricular activity is maintained by an escape rhythm arising in the AV node or bundle of His (narrow QRS complexes) or the distal Purkinje tissues (broad QRS complexes). Distal escape rhythms tend to be slower and less reliable. Complete AV block (Box 16.27) produces a slow (25–50/min), regular pulse that does not vary with exercise, except in the case of congenital complete AV block. There is usually a compensatory increase in stroke volume, producing a large-volume pulse. Cannon waves may be visible in the neck and the intensity of the first heart sound varies due to the loss of AV synchrony.
Patients with symptomatic bradyarrhythmias associated with AV block should be treated with a permanent pacemaker. Asymptomatic first-degree or Mobitz type I second-degree AV block (Wenckebach phenomenon) does not require treatment but may be an indication of underlying heart disease. A permanent pacemaker is usually indicated in patients with asymptomatic Mobitz type II second-degree AV block or third-degree AV heart block because of the risk of asystole and sudden death. Pacing improves prognosis.

**Bundle branch block**

Damage to the right or left bundle branch of the conducting system can occur as a result of many pathologies, including ischaemic heart disease, hypertensive heart disease and cardiomyopathy. However, right bundle branch block (RBBB) can occur as a normal variant in healthy individuals (Box 16.28). In left bundle branch block (LBBB) and RBBB, depolarisation proceeds through a slow myocardial route in the affected ventricle rather than through the rapidly conducting Purkinje tissues that constitute the bundle branches. This causes delayed conduction into the LV or RV, broadens the QRS complex (≥0.12 sec) and produces characteristic alterations in QRS morphology (Figs 16.49 and 16.47).

**Common causes of bundle branch block**

- **Right bundle branch block**
  - Normal variant
  - Right ventricular hypertrophy or strain, e.g. pulmonary embolism
  - Congenital heart disease, e.g. atrial septal defect
  - Coronary artery disease

- **Left bundle branch block**
  - Coronary artery disease
  - Hypertension
  - Aortic valve disease
  - Cardiomyopathy

**Fig. 16.47** Second-degree atrioventricular block with fixed 2:1 block. Alternate P waves are not conducted. This may be due to Mobitz type I or II block.

**Fig. 16.48** Complete (third-degree) atrioventricular block. There is complete dissociation of atrial and ventricular complexes. The atrial rate is 80/min and the ventricular rate is 38/min.

**16.27 Causes of complete atrioventricular block**

- **Congenital**
- **Acquired**
  - Idiopathic fibrosis
  - Myocardial infarction/ischaemia
  - Inflammation:
    - Infective endocarditis
    - Sarcoidosis
    - Chagas’ disease
  - Trauma
  - Drugs:
    - Digoxin
    - β-blockers
    - Calcium antagonists

**Fig. 16.49** Right bundle branch block. Note the wide QRS complexes with ‘M’-shaped configuration in leads V1 and V6 and a wide S wave in lead I.

loss of consciousness that occurs without warning and results in collapse. A brief anoxic seizure (due to cerebral ischaemia) may occur if there is prolonged asystole. There is pallor and a death-like appearance during the attack, but when the heart starts beating again there is a characteristic flush. In distinction to epilepsy, recovery is rapid. Sinoatrial disease and neurocardiogenic syncope (p. 181) may cause similar symptoms.

**Management**

This depends on the clinical circumstances. Acute inferior MI is often complicated by transient AV block because the right coronary artery (RCA) supplies the AV node. There is usually a reliable escape rhythm and, if the patient remains well, no treatment is required. Symptomatic second- or third-degree AV block may respond to atropine (0.6 mg IV, repeated as necessary) or, if this fails, a temporary pacemaker. In most cases, the AV block will resolve within 7–10 days.

Second- or third-degree AV heart block complicating acute anterior MI indicates extensive ventricular damage involving both bundle branches and carries a poor prognosis. Asystole may ensue and a temporary pacemaker should be inserted promptly. If the patient presents with asystole, intravenous atropine (3 mg) or intravenous isoprenaline (2 mg in 500 mL 5% dextrose, infused at 10–60 mL/hr) may help to maintain the circulation until a temporary pacing electrode can be inserted. Temporary pacing can provide effective rhythm support in the short term.
Principles of management of cardiac arrhythmias

Cardiac arrhythmias can be managed with either anti-arrhythmic drug therapy or external devices that depolarise the heart by passing an electric current through it. These strategies are relevant across a range of indications and are discussed in more detail here.

Anti-arrhythmic drugs

Traditionally, the Vaughan Williams system has been used to categorise anti-arrhythmic drugs based on their effects on the action potential. More recently, increased understanding of the mechanisms of action has allowed further subclassification, based on the cardiac ion channels and receptors on which they act (Box 16.29 and Fig. 16.51). The individual agents, dosages and most common side-effects are summarised in Box 16.30 and the general principles of use are summarised in Box 16.31.

Class I drugs

Class I drugs act principally by suppressing excitability and slowing conduction in atrial or ventricular muscle. They block sodium channels, of which there are several types in cardiac tissue. These drugs should generally be avoided in patients with heart failure because they depress myocardial function, and class Ia and Ic drugs are often pro-arrhythmic.

Class Ia drugs

These prolong cardiac action potential duration and increase the tissue refractory period. They are used to prevent both atrial and ventricular arrhythmias.

Disopyramide

This is an effective drug but causes anticholinergic side-effects, such as urinary retention, and can precipitate glaucoma. It can...
Lidocaine
This must be given intravenously and has a very short plasma half-life.

Mexiletine
This can be given intravenously or orally but has many side-effects.

### Class Ib drugs

These shorten the action potential and tissue refractory period. They act on channels found predominantly in ventricular myocardium and so are used to treat or prevent VT and VF.

### Class Ic drugs

These affect the slope of the action potential without altering its duration or refractory period. They are used mainly for prophylaxis of AF but are effective in prophylaxis and treatment of depression myocardial function and should be avoided in cardiac failure.

**Quinidine**

Now rarely used, quinidine increases mortality and causes gastrointestinal upset.

*Sotalol also has class II activity as a β-blocker.
(AF = atrial fibrillation; IV = intravenous; SR = sustained-release formulation; SVT = supraventricular tachycardia; VE = ventricular ectopic; VF = ventricular fibrillation; VT = ventricular tachycardia)*
Anti-arrhythmic drugs are potentially toxic and should be used carefully according to the following principles:

- Many arrhythmias are benign and do not require specific treatment
- Precipitating or causal factors should be corrected if possible:
  - Alcohol excess
  - Caffeine consumption
  - Myocardial ischaemia
  - Hypothyroidism
  - Acidosis
  - Hypokalaemia
  - Hypomagnesaemia
- If drug therapy is required, it is best to use as few drugs as possible.
- In difficult cases, programmed electrical stimulation (electrophysiological study) may help to identify the optimum therapy.
- When managing life-threatening arrhythmias, it is essential to ensure that prophylactic treatment is effective. Ambulatory monitoring and exercise testing may be of value.
- Patients on long-term anti-arrhythmic drugs should be reviewed regularly and attempts made to withdraw therapy if the factors that precipitated the arrhythmias are no longer operative.
- For patients with recurrent supraventricular tachycardia, radiofrequency ablation is often preferable to long-term drug therapy.

These act mainly on myocardial β1 receptors and are relatively well tolerated. Bisoprolol and metoprolol are examples of cardioselective β-blockers.

Sotalol

This is a racemic mixture of two isomers with non-selective β-blocker (mainly l-sotalol) and class III (mainly d-sotalol) activity. It may cause torsades de pointes.

Class III drugs

Class III drugs act by prolonging the plateau phase of the action potential, thus lengthening the refractory period. These drugs are very effective at preventing atrial and ventricular tachyarrhythmias. They cause QT interval prolongation and can predispose to torsades de pointes and VT, especially in patients with other predisposing risk factors (see Box 16.26). Disopyramide and sotalol have some class III activity but the main drug in this class is amiodarone, as discussed below.

Amiodarone

While amiodarone is primarily considered a class III drug, it also has class I, II and IV activity. It is probably the most effective drug currently available for controlling paroxysmal AF. It is also used to prevent episodes of recurrent VT, particularly in patients with poor left ventricular function or those with implantable defibrillators (to prevent unnecessary DC shocks). Amiodarone has a very long tissue half-life (25–110 days). An intravenous or oral loading regime is often used to achieve therapeutic tissue concentrations rapidly. The drug’s effects may last for weeks or months after treatment has been stopped. Side-effects are common (up to one-third of patients), numerous and potentially serious. Drug interactions are also common (see Box 16.30).

Dronedarone

Dronedarone is related to amiodarone but has a short tissue half-life and fewer side-effects. It has recently been shown to be effective at preventing episodes of atrial flutter and AF. It is contraindicated in patients with permanent AF, or if there is heart failure or left ventricular impairment, because it increases mortality. Regular liver function test monitoring is required.

Class IV drugs

These block the ‘slow calcium channel’, which is important for impulse generation and conduction in atrial and nodal tissue, although it is also present in ventricular muscle. Their main indications are prevention of SVT (by blocking the AV node) and rate control in patients with AF.

Verapamil

This is the most widely used drug in this class. Intravenous verapamil may cause profound bradycardia or hypotension, and should not be used in conjunction with β-blockers.

Diltiazem

This has similar properties to verapamil.

Other anti-arrhythmic drugs

Atropine sulphate

Atropine is a muscarinic receptor antagonist that increases the sinus rate and SA and AV conduction. It is the treatment of choice for severe bradycardia or hypotension due to vagal over-activity. It is used for initial management of symptomatic bradyarrhythmias complicating inferior MI, and in cardiac arrest due to asystole. The usual dose is 0.6 mg IV, repeated if necessary.
to a maximum of 3 mg. Repeat dosing may be necessary because the drug disappears rapidly from the circulation after parenteral administration. Side-effects are listed in Box 16.30.

Adenosine
This works by binding to A1 receptors in conducting tissue, producing a transient AV block lasting a few seconds. It is used to terminate SVTs when the AV node is part of the re-entry circuit, or to help establish the diagnosis in difficult arrhythmias, such as atrial flutter with 2:1 AV block (see Fig. 16.35) or broad-complex tachycardia (Boxes 16.30 and 16.32). Adenosine is given as an intravenous bolus, initially 3 mg over 2 secs (see Box 16.30). If there is no response after 1–2 minutes, 6 mg should be given; if necessary, after another 1–2 minutes the maximum dose of 12 mg may be given. Patients should be warned to expect short-lived and sometimes distressing flushing, breathlessness and chest pain. Adenosine can cause bronchospasm and should be avoided in patients with asthma; its effects are greatly potentiated by dipyridamole and inhibited by theophylline and other xanthines.

Digoxin
Digoxin is a glycoside purified from the European foxglove, _Digitalis lanata_, which slows conduction and prolongs the refractory period in the AV node. This effect helps to control the ventricular rate in AF and may interrupt SVTs involving the AV node. Digoxin also shortens refractory periods and enhances excitability and conduction in other parts of the heart, including accessory conduction pathways. It may therefore increase atrial and ventricular ectopic activity and can lead to more complex atrial and ventricular tachyarrhythmias. Digoxin is largely excreted by the kidneys, and the maintenance dose (see Box 16.30) should be reduced in children, older people and those with renal impairment. It is widely distributed and has a long tissue half-life (36 hours), so that effects may persist for several days. Measurement of plasma digoxin concentration helps identify digoxin toxicity or under-treatment (Box 16.33).

Non-pharmacological treatments
A variety of non-pharmacological treatments are available for the treatment of arrhythmias. These include the use of electrical devices that work by passing an electric current through the heart, and catheter-based strategies that disrupt abnormal conduction tissues responsible for the generation of arrhythmias.

**Electrical cardioversion**

Electrical cardioversion, also known as direct current (DC) cardioversion, is useful for terminating an organised rhythm, such as AF or VT. The electric current interrupts the arrhythmia and produces a brief period of asystole, which is usually followed by the resumption of sinus rhythm. Cardioversion is usually carried out as an elective procedure under general anaesthesia. The electric shock is delivered immediately after the R wave because, if it is applied during ventricular repolarisation (on the T wave), it may provoke VF. High-energy shocks may cause chest wall pain post-procedure, so, if there is no urgency, it is appropriate to begin with a lower-amplitude shock of about 50 joules initially, going on to larger shocks if necessary.

**Defibrillation**

Defibrillators deliver a DC, high-energy, short-duration shock via two large electrodes or paddles coated with conducting jelly or a gel pad, positioned over the upper right sternal edge and the apex. Defibrillators are primarily used in the management of cardiac arrest due to VF and deliver an unsynchronised shock, since the precise timing of the discharge is not important in this situation. Modern units deliver a biphasic shock, during which the shock polarity is reversed mid-shock. This reduces the total shock energy required to depolarise the heart. In VF and other emergencies, the energy of the first and second shocks should be 150 joules and thereafter up to 200 joules; there is no need for an anaesthetic, as the patient is unconscious.

**Temporary pacemakers**

Temporary pacing involves delivery of an electrical impulse into the heart to initiate tissue depolarisation and to trigger cardiac contraction. This is achieved by inserting a bipolar pacing electrode through the internal jugular, subclavian or femoral vein and positioning it at the apex of the RV, using fluoroscopic imaging. The electrode is connected to an external pacemaker with an adjustable energy output and pacing rate. The ECG of right ventricular pacing is characterised by regular broad QRS complexes with a left bundle branch block pattern. Each complex is immediately preceded by a ‘pacing spike’ (Fig. 16.52). Nearly all pulse generators are used in the ‘demand’ mode, so that the pacemaker will operate only if the heart rate falls below a preset level. Occasionally, temporary atrial or dual-chamber pacing (see below) is used.

Temporary pacing is indicated in the management of transient AV block and other arrhythmias complicating acute MI or cardiac surgery, to maintain the rhythm in other situations of reversible bradycardia (such as metabolic disturbance or drug overdose), or as a bridge to permanent pacing. Complications include pneumothorax, brachial plexus or subclavian artery injury, local infection or sepsis (usually with _Staphylococcus aureus_), and pericarditis. Failure of the system may be due to lead displacement or a progressive increase in the threshold (exit block) caused by tissue oedema. Complication rates increase with time and so a temporary pacing system should ideally not be used for more than 7 days.

Transcutaneous pacing is administered by delivering an electrical stimulus through two large adhesive gel pad electrodes...
placed over the apex and upper right sternal edge, or over the anterior and posterior chest. It is easy and quick to set up, but causes discomfort because it induces forceful pectoral and intercostal muscle contraction. Modern external cardiac defibrillators often incorporate a transcutaneous pacing system that can be used during an emergency until transvenous pacing is established.

**Permanent pacemakers**

Permanent pacemakers are small, flat, metal devices that are implanted under the skin, usually in the pectoral area. They contain a battery, a pulse generator, and programmable electronics that allow adjustment of pacing and memory functions. Pacing electrodes (leads) can be placed via the subclavian or cephalic veins into the RV (usually at the apex), the right atrial appendage or, to maintain AV synchrony, both. Permanent pacemakers are controlled using an external programmer through a wireless telemetry system, allowing rate, output, timing and other parameters to be adjusted. This allows the device settings to be tailored to the patient’s needs. Aside from their therapeutic role, pacemakers store useful diagnostic data about the patient’s heart rate trends and the occurrence of tachyarrhythmias, such as VT.

Single-chamber atrial pacing is indicated in patients with SA disease without AV block and also in patients with continuous AF and bradycardia. Here the pacemaker acts as an external sinus node. Dual-chamber pacing is most often used in patients with second- or third-degree AV block. Here, the atrial electrode is used to detect spontaneous atrial activity and trigger ventricular pacing (Fig. 16.52), thereby preserving AV synchrony and allowing the ventricular rate to increase, together with the sinus node rate, during exercise and other forms of stress. Dual-chamber pacing has many advantages over ventricular pacing, including superior haemodynamics and better effort tolerance; a lower prevalence of atrial arrhythmias in patients with SA disease; and avoidance of ‘pacemaker syndrome’, in which a fall in BP and dizziness occur due to loss of AV synchrony.

A code is used to signify the pacing mode (Box 16.34). For example, a system that paces the atrium, senses the atrium and is inhibited if it senses spontaneous activity is designated AAI. Most dual-chamber pacemakers are programmed to a mode termed DDD; in this case, ventricular pacing is triggered by a sensed sinus P wave and inhibited by a sensed spontaneous QRS complex. A fourth letter, ‘R’, is added if the pacemaker has a rate response function. For example, the letters AAIR indicate an atrial demand pacemaker with a rate response function. Rate-responsive pacemakers are used in patients with chronotropic incompetence, who are unable to increase their heart rate during exercise. These devices have a sensor that triggers an increase in heart rate in response to movement or increased respiratory rate. The sensitivity of the sensor is programmable, as is the maximum paced heart rate.

Early complications of permanent pacing include pneumothorax, cardiac tamponade, infection and lead displacement. Late complications include infection (which usually necessitates removing the pacing system), erosion of the generator or lead, chronic pain related to the implant site, and lead fracture due to mechanical fatigue.

**Implantable cardiac defibrillators**

In addition to the functions of a permanent pacemaker, implantable cardiac defibrillators (ICDs) can also detect and terminate life-threatening ventricular tachyarrhythmias. ICDs are larger than pacemakers mainly because of the need for a large battery and capacitor to enable cardioversion or defibrillation. ICD leads are similar to pacing leads but have one or two shock coils along the length of the lead, used for delivering defibrillation. ICDs treat ventricular tachyarrhythmias using overdrive pacing, cardioversion or defibrillation. They are implanted in a similar manner to pacemakers and carry a similar risk of complications. In addition, patients can be prone to psychological problems and anxiety, particularly if they have experienced repeated shocks from their device.

The evidence-based indications for ICD implantation are shown in Box 16.35. These can be divided into secondary prevention indications, when patients have already had a potentially life-threatening ventricular arrhythmia, and primary prevention indications, when patients are considered to be at significant future risk of arrhythmic death. A common primary prevention indication is in patients with inherited conditions associated with a high risk of sudden cardiac death, such as long QT syndrome (p. 476), hypertrophic cardiomyopathy (p. 539) and arrhythmogenic right ventricular dysplasia (p. 540). Treatment with ICDs is expensive.
and so the indications for which the devices are routinely implanted depend on the health-care resources available.

### Cardiac resynchronisation therapy

Cardiac resynchronisation therapy (CRT) is a useful treatment for selected patients with heart failure, in whom cardiac function is impaired by the presence of left bundle branch block. This conduction defect is associated with poorly coordinated left ventricular contraction that can aggravate heart failure in susceptible patients. The systems used to deliver CRT comprise a right atrial lead, a right ventricular lead, and a third lead that is placed via the coronary sinus into one of the veins on the epicardial surface of the LV (see Fig. 16.30, p. 467). Simultaneous septal and left ventricular epicardial pacing resynchronises left ventricular contraction.

CRT improves symptoms and quality of life, and reduces mortality in patients with moderate to severe (NYHA class III–IV) heart failure who are in sinus rhythm, with left bundle branch block and left ventricular ejection fraction of 35% or less. CRT also prevents heart failure progression in similar patients with mild (NYHA class I–II) heart failure symptoms. These devices are more effective in patients in sinus rhythm than in those with AF. Most devices are also defibrillators (CRT-D) because many patients with heart failure are predisposed to ventricular arrhythmias. CRT pacemakers (CRT-P) are used when the focus is palliation of symptoms rather than prolonging life.

### Catheter ablation therapy

Catheter ablation therapy is the treatment of choice for patients with SVT or atrial flutter, and is a useful treatment for some patients with AF or ventricular arrhythmias (Fig. 16.53). It involves inserting a series of catheter electrodes into the heart through the venous system. These are used to record the activation sequence of the heart in sinus rhythm, during tachycardia and after pacing manoeuvres. Once the arrhythmia focus or circuit, such as an accessory pathway in WPW syndrome, has been identified, a catheter is used to ablate the culprit tissue. This can be done either by using heat, which is termed radiofrequency ablation, or by freezing, which is termed cryoablation. The procedure takes approximately 1–4 hours and does not require a general anaesthetic, although the patient may experience some discomfort during the ablation procedure. Serious complications are rare (<1%) but include complete heart block requiring pacemaker implantation, and cardiac tamponade. For many arrhythmias, radiofrequency ablation is very attractive because it offers the prospect of a lifetime cure, thereby eliminating the need for long-term drug therapy.

The technique has revolutionised the management of many arrhythmias and is now the treatment of choice for AVNRT and AV re-entrant (accessory pathway) tachycardias, when it is curative in over 90% of cases. Focal atrial tachycardias and atrial flutter can also be treated by radiofrequency ablation, although some patients subsequently experience episodes of AF. The applications of the technique are expanding and it can now be used to treat some forms of VT. Catheter ablation techniques are also employed to prevent AF. This involves ablation at two sites: the ostia of the pulmonary veins, from which ectopic beats may trigger paroxysms of arrhythmia, and in the LA itself, where re-entry circuits maintain AF. Once established. This is effective at reducing episodes of AF in around 70–80% of younger patients with structurally normal hearts, and tends to be reserved for patients with drug-resistant AF because the procedure carries a risk of cardiac tamponade, and rarely stroke or death.

In patients with permanent AF and poor rate control, in whom drugs are ineffective or are not tolerated, rate control can be achieved by implantation of a permanent pacemaker, followed by ablation of the AV node to induce complete AV block and bradycardia, thus allowing the pacemaker to assume control of the heart rate.

### Coronary artery disease

Coronary artery disease (CAD) is the most common cause of angina and acute coronary syndrome and the most common cause of death worldwide. The World Health Organisation (WHO) has estimated that 3.8 million men and 3.4 million women die from cardiovascular disease (CVD) each year, and since 1990, more people have died from CVD than any other cause. It also has a devastating effect on quality of life. Disability-adjusted life years, a measure of healthy years of life lost, can be used to indicate the burden of disease rather than the resulting deaths. It has been estimated that CAD is responsible for 10% of disability-adjusted life years in low-income countries and 18% in high-income ones. In the UK, 1 in 3 men and 1 in 4 women die from CAD, an estimated 188,000 people have a myocardial infarct each year, and approximately 2.3 million people are living with CAD. The death rates from CAD in the UK are among the highest in Western Europe (more than 70,000 people) but are falling, particularly in younger age groups; over the last 50 years, CAD mortality has more than halved. In Eastern Europe and much of Asia, however, the rates of CAD are rapidly rising. Occult CAD is common in those who present with other forms of atherosclerotic vascular disease, such as intermittent claudication or stroke, and is an important cause of morbidity and mortality in these patients.

#### Pathogenesis

In the vast majority of patients, CAD is caused by atherosclerosis (Box 16.36) but rarely it can occur as the result of aortitis (p. 508), vasculitis (p. 1040) and autoimmune connective tissue diseases (p. 1034). Atherosclerosis is a progressive inflammatory disorder of the arterial wall that is characterised by focal lipid-rich deposits of atheroma that remain clinically silent until they become large enough to impair tissue perfusion, or until ulceration and disruption...
of the lesion result in thrombotic occlusion or distal embolisation of the vessel. Atherosclerosis begins early in life with deposits of lipids in the vessel wall, which tend to occur at sites of altered arterial shear stress, such as bifurcations, and are associated with abnormalities of endothelial function at that site. Abnormalities of arterial function have been detected among high-risk children and adolescents, such as cigarette smokers and those with familial hyperlipidaemia or hypertension. Early lesions have been found in the arteries of victims of accidental death in the second and third decades of life but clinical manifestations often do not appear until the sixth, seventh or eighth decade. During evolution of an atherosclerotic plaque, monocytes and other inflammatory cells bind to receptors expressed by endothelial cells. Subsequently, they migrate into the intima, and take up oxidised low-density lipoprotein (LDL) particles by phagocytosis to become lipid-laden macrophages or foam cells. Extracellular lipid pools appear in the intimal space when foam cells die and release their contents (Fig. 16.54). In response to cytokines and growth factors produced by activated macrophages, smooth muscle cells migrate from the media of the arterial wall into the intima, and change from a contractile to a fibroblastic phenotype, which can stabilise the atherosclerotic lesion. If this is successful, the lipid core will be covered by smooth muscle cells and matrix, producing a stable atherosclerotic plaque that will remain asymptomatic until it becomes large enough to obstruct arterial flow.

In an established atherosclerotic plaque, macrophages mediate inflammation and smooth muscle cells promote repair. If inflammation predominates, the plaque becomes active or unstable and may be complicated by ulceration and thrombosis. Cytokines, such as interleukin-1, tumour necrosis factor-alpha, interferon-gamma, platelet-derived growth factors and matrix metalloproteinases, are released by activated macrophages. They cause the intimal smooth muscle cells overlying the plaque to become senescent and the collagen cross-links within the plaque to degrade. This results in thinning of the protective fibrous cap, making the lesion vulnerable to mechanical stress that ultimately causes erosion, fissuring or rupture of the plaque surface (Fig. 16.54). Any breach in the integrity of the plaque will expose its contents to blood and will trigger platelet aggregation and

---

### Clinical problem | Pathology
---|---
Stable angina | Ischaemia due to fixed atheromatous stenosis of one or more coronary arteries
Unstable angina | Ischaemia caused by dynamic obstruction of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Myocardial infarction | Myocardial necrosis caused by acute occlusion of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Heart failure | Myocardial dysfunction due to infarction or ischaemia
Arrhythmia | Altered conduction due to ischaemia or infarction
Sudden death | Ventricular arrhythmia, asystole or massive myocardial infarction

---

thrombosis that extend into the atheromatous plaque and the arterial lumen. This may cause partial or complete obstruction at the site of the lesion or distal embolisation, resulting in infarction or ischaemia of the affected organ. This common mechanism underlies acute coronary syndromes, as well as other manifestations of atherosclerotic disease such as lower limb ischaemia (p. 502) and stroke (Ch. 26).

The number and complexity of arterial plaques increase with age and risk factors (see below) but the rate of progression of individual plaques is variable. There is a complex and dynamic interaction between mechanical wall stress and atherosclerotic lesions. Vulnerable plaques are characterised by a lipid-rich core, a thin fibrocellular cap, speckled calcification and an increase in inflammatory cells that release specific enzymes to degrade matrix proteins. In contrast, stable plaques are typified by a small lipid pool, a thick fibrous cap, heavy calcification and plentiful collagenous cross-links. Fissuring or rupture tends to occur at sites of maximal mechanical stress, particularly the margins of an eccentric plaque, and may be triggered by a surge in BP, such as during exercise or emotional stress. Surprisingly, most plaque events are subclinical and heal spontaneously, although this may allow thrombus to be incorporated into the lesion, producing plaque growth and further obstruction to flow.

Atherosclerosis may induce complex changes in the media that lead to arterial remodelling. Some arterial segments may slowly constrict (negative remodelling), while others may gradually enlarge (positive remodelling). These changes are important because they may amplify or minimise the degree to which atheroma encroaches into the arterial lumen.

Many risk factors have been identified for atherosclerosis but the causes are incompletely understood, since unknown factors account for up to 40% of the variation in risk from one person to the next.

Age and sex
Age is the most powerful independent risk factor for atherosclerosis and gender also plays a role. Pre-menopausal women have lower rates of disease than men, although the gender difference disappears after the menopause. Hormone replacement therapy (HRT) is not effective in the prevention of CAD, and HRT in post-menopausal women is associated with an increased risk of cardiovascular events.

Genetics
Atherosclerotic CAD often runs in families and a positive family history is common in patients with early-onset disease (age <50 in men and <55 in women). Twin studies have shown that a monozygotic twin of an affected individual has an eightfold increased risk and a dizygotic twin a fourfold increased risk of dying from CAD, compared to the general population due to a combination of shared genetic, environmental and lifestyle factors. The most common risk factors, such as hypertension, hyperlipidaemia and diabetes mellitus, are inherited in a polygenic manner.

Smoking
There is a strong relationship between cigarette smoking and CAD, especially in younger (<70 years) individuals, and this is probably the most important modifiable risk factor.

Hypertension
The incidence of atherosclerosis increases as BP rises, and this is related to systolic and diastolic BP, as well as pulse pressure.

Antihypertensive therapy reduces cardiovascular mortality, stroke and heart failure.

Hypercholesterolaemia
The risk of atherosclerosis rises with serum cholesterol concentrations and lowering serum total and LDL cholesterol concentrations reduces the risk of cardiovascular events.

Diabetes mellitus
This is a potent risk factor for all forms of atherosclerosis, especially type 2 diabetes mellitus. It is often associated with diffuse disease that is difficult to treat. Insulin resistance (normal glucose homeostasis with high levels of insulin) is associated with obesity and physical inactivity, and is also a risk factor for CAD (p. 730). Glucose intolerance makes a major contribution to the high incidence of ischaemic heart disease in people from the Indian subcontinent and some other ethnic groups.

Haemostatic factors
Platelet activation and high plasma fibrinogen concentrations are associated with an increased risk of coronary thrombosis, whereas antiphospholipid antibodies are associated with recurrent arterial thromboses (p. 977).

Physical activity
Regular exercise (brisk walking, cycling or swimming for 20 minutes two or three times a week) has a protective effect, whereas inactivity roughly doubles the risk of CAD and is a major risk factor for stroke.

Obesity
Obesity, particularly if central or truncal, is an independent risk factor, although it is often associated with other adverse factors such as hypertension, diabetes mellitus and physical inactivity.

Alcohol
Excess alcohol consumption is associated with hypertension and cerebrovascular disease.

Diet
Diets deficient in fresh fruit, vegetables and polyunsaturated fatty acids are associated with an increased risk of cardiovascular disease. The introduction of a Mediterranean-style diet reduces cardiovascular events. However, dietary supplements, such as vitamins C and E, beta-carotene, folate and fish oils, do not reduce cardiovascular events and, in some cases, have been associated with harm.

Personality
While certain personality traits are associated with an increased risk of coronary disease there is no evidence to support the popular belief that stress is a major cause of CAD.

Social deprivation
Social deprivation is strongly related to cardiovascular disease. This may be partly due to associations with lifestyle risk factors, such as smoking and alcohol excess, which are more common in socially deprived individuals. Social deprivation does appear to be an independent risk factor for cardiovascular disease, however. Current guidelines recommend that treatment thresholds should be lowered for patients from socially deprived areas.
The effect of risk factors can be multiplicative rather than additive. People with a combination of risk factors are at greatest risk and so assessment should take account of all identifiable risk factors. It is important to distinguish between relative risk (the proportional increase in risk) and absolute risk (the actual chance of an event). For example, a man of 35 years with a plasma cholesterol of 7 mmol/L (approximately 170 mg/dL), who smokes 40 cigarettes a day, is much more likely to die from coronary disease within the next decade than a non-smoking man of the same age with a normal cholesterol, but the absolute likelihood of his dying during this time is still small (high relative risk, low absolute risk).

Management

Two approaches can be employed. Primary prevention aims to introduce lifestyle changes or therapeutic interventions to prevent CAD and other forms of atherosclerosis in the whole population or in healthy individuals with an elevated risk of disease. Secondary prevention involves initiating treatment in patients who already have had an event, with the aim of reducing the risk of subsequent events.

Primary prevention

The population-based strategy aims to modify the risk factors of the whole population through diet and lifestyle advice, on the basis that even a small reduction in smoking or average cholesterol, or modification of exercise and diet will produce worthwhile benefits (Box 16.37). Some risk factors, such as obesity and smoking, are also associated with a higher risk of other diseases and should be actively discouraged through public health measures. The effectiveness of this approach has been demonstrated by introduction of legislation to restrict smoking in public places, which has been associated with reductions in rates of MI.

The targeted strategy aims to identify and treat high-risk individuals, who usually have a combination of risk factors that can be quantified by composite scoring systems. It is important to consider the absolute risk of atheromatous cardiovascular disease that an individual is facing before initiating treatment, since this will help to determine whether the potential benefits of intervention are likely to outweigh the expense, inconvenience and possible side-effects of treatment. For example, a 65-year-old man with an average BP of 150/90 mmHg, who smokes and has diabetes mellitus with a total/high-density lipoprotein (HDL) cholesterol ratio of 8, has a 10-year risk of MI or stroke of 56%. Conversely, a 55-year-old woman who has an identical BP, is a non-smoker, does not have diabetes mellitus, and has a total/HDL cholesterol ratio of 6 has a much better outlook, with a 10-year coronary MI or stroke risk of 5.7%. Lowering cholesterol will reduce the risk in both of these individuals by 30% and lowering BP will produce a further 20% reduction. In combination, both strategies would reduce the risk of an event from 56% to 25% in the male patient and from 5.7% to 2.5% in the female patient. Thresholds for treatment vary in different countries. In the UK and North America, current guidelines recommend initiation of cholesterol and BP-lowering therapies in individuals with a 10-year cardiovascular risk of 7.5–10%.

Secondary prevention

This involves targeting interventions at individuals who already have evidence of cardiovascular disease. Patients who recover from a clinical event such as an MI are usually keen to help themselves and are particularly receptive to lifestyle advice, such as dietary modification and smoking cessation. Additional interventions that should be introduced in patients with angina pectoris or an acute coronary syndrome are discussed in more detail below.

Angina pectoris

Angina pectoris is a symptom complex caused by transient myocardial ischaemia, which occurs whenever there is an imbalance between myocardial oxygen supply and demand (Box 16.38).

Pathogenesis

Atherosclerosis is by far the most common cause of angina pectoris. Angina may also occur in aortic valve disease and hypertrophic cardiomyopathy, and when the coronary arteries are involved with vasculitis or aortitis. The underlying mechanisms and risk factors for atherosclerosis have already been discussed. Approximately 10% of patients who report stable angina on effort have normal coronary arteries on angiography. The main causes are discussed in more detail below.

Coronary artery spasm

Angina may result from vasospasm of the coronary arteries. This may coexist with atherosclerosis, especially in unstable angina (see below), but may occur as an isolated phenomenon in less than 1% of cases, in patients with normal coronary arteries on angiography. This is sometimes known as variant angina; when it is accompanied by transient ST elevation on the ECG, it is termed Prinzmetal’s angina.

Syndrome X

The constellation of typical angina on effort, objective evidence of myocardial ischaemia on stress testing, and normal coronary arteries on angiography is sometimes known as syndrome X. Many of these patients are women and the mechanism of their

### 16.37 Population-based strategies to prevent coronary disease

- Do not smoke
- Take regular exercise (minimum of 20 mins, three times per week)
- Maintain an ‘ideal’ body weight
- Eat a mixed diet rich in fresh fruit and vegetables
- Aim to get no more than 10% of energy intake from saturated fat

### 16.38 Factors influencing myocardial oxygen supply and demand

#### Oxygen demand: cardiac work

- Heart rate
- Blood pressure
- Myocardial contractility

#### Oxygen supply: coronary blood flow

- Duration of diastole
- Coronary perfusion pressure (aortic diastolic minus coronary sinus or right atrial diastolic pressure)
- Coronary vasomotor tone
- Oxgenation: Haemoglobin
- Oxygen saturation

*Coronary blood flow occurs mainly in diastole.*
symptoms is often unclear. This disorder is poorly understood; it carries a good prognosis but may respond to anti-anginal therapy.

Other causes
Angina can occur in association with aortic stenosis, hypertrophic obstructive cardiomyopathy and aortitis, all of which are discussed in more detail later in this chapter. It may also rarely be found in association with vasculitis (p. 1040).

Clinical features
The history is the most important factor in making the diagnosis (p. 454). Stable angina is characterised by central chest pain, discomfort or breathlessness that is predictably precipitated by exertion or other forms of stress (Box 16.39), and is promptly relieved by rest (see Fig. 10.1, p. 179). Some patients find the discomfort comes when they start walking and that later it does not return despite greater effort (‘warm-up angina’). The Canadian Cardiovascular Society (CCS) scoring system is commonly used to grade the severity of angina (Box 16.40). This is of clinical value, not only in documenting the severity of angina but also in assessing prognosis (p. 493).

Physical examination is frequently unremarkable but should include a careful search for evidence of valve disease (particularly aortic), important risk factors (hypertension, diabetes mellitus), left ventricular dysfunction (cardiomegaly, gallop rhythm), other manifestations of arterial disease (carotid bruits, peripheral arterial disease), and unrelated conditions that may exacerbate angina (anaemia, thyrotoxicosis).

Investigations
Symptoms are a poor guide to the extent of CAD. Because of this, stress testing and non-invasive imaging are advisable in patients who are potential candidates for revascularisation. An algorithm for the investigation and treatment of patients with stable angina is shown in Figure 16.55. The first-line investigation is an exercise ECG, which should be performed using a standard treadmill or bicycle ergometer protocol (p. 449) while monitoring the patient’s pulse, BP and general condition. Planar or down-sloping ST segment depression of 1 mm or more is indicative of ischaemia (Fig. 16.56). Up-sloping ST depression is less specific; it often occurs in normal individuals and false-positive results can occur with digitalis therapy, left ventricular hypertrophy, bundle branch block and WPW syndrome. The amount of exercise that can be tolerated and the extent of ST segment change (Fig. 16.57) that occurs can be of value in identifying high-risk individuals with severe coronary disease in combination with other clinical features (Box 16.41). However, exercise testing may be normal in a significant proportion of patients with CAD or may be inconclusive because an adequate heart rate cannot be achieved due to reduced mobility or other non-cardiac problems. Accordingly, if clinical suspicion is high and the exercise ECG is normal or inconclusive, further imaging with myocardial perfusion scanning or stress echocardiography is indicated. A perfusion defect present during stress but not at rest provides evidence of reversible myocardial ischaemia (Fig. 16.58), whereas a persistent perfusion defect seen during both phases of the study is usually indicative of previous MI. Increasingly, CT coronary arteriography is being used to document the presence or absence of CAD in patients with suspected angina. It can clarify the diagnosis, help to guide optimal treatment and avoid the need for cardiac catheterisation in patients who do not have CAD or who have mild disease only (see Fig. 16.55).

Coronary angiography provides detailed anatomical information about the extent and nature of CAD (see Fig. 16.15, p. 453). It is usually performed when coronary artery bypass graft surgery or percutaneous coronary intervention is being considered (p. 491).

Management
This should begin with a careful explanation of the problem and a discussion of the lifestyle and medical interventions that can be deployed to relieve symptoms and improve prognosis (Box 16.42). Anxiety and misconceptions often contribute to disability; for example, some patients avoid all forms of exertion because they believe that each attack of angina is a ‘mini-heart attack’ that results in permanent damage. Education and reassurance can dispel these misconceptions and make a huge difference to the patient’s quality of life.

The principles of management involve:
- a careful assessment of the extent and severity of arterial disease
- identification and treatment of risk factors
- advice on smoking cessation
- introduction of drug treatment for symptom control
- identification of high-risk patients for treatment to improve life expectancy.
Fig. 16.55 A scheme for the investigation and treatment of stable angina on effort. This scheme is best adopted for patients without prior known coronary artery disease. For patients with known coronary artery disease, further stress imaging (echocardiography, radionuclide perfusion or magnetic resonance perfusion) rather than computed tomography coronary angiography is recommended.

All patients with angina secondary to CAD should receive antiplatelet therapy. Low-dose (75 mg) aspirin should be prescribed for all patients and continued indefinitely since it reduces the risk of MI. Clopidogrel (75 mg daily) is an equally effective alternative if aspirin causes dyspepsia or other side-effects. Similarly, all patients should be prescribed a statin, even if cholesterol is normal.

**Anti-anginal drug therapy**

The goal of anti-anginal therapy is to control symptoms using a regimen that is as simple as possible and does not cause side-effects. Five groups of drug can be used in the prevention and treatment of angina but there is little evidence that one group is more effective than another. It is conventional to start therapy with sublingual glyceryl trinitrate (GTN) and a β-blocker, and then add a calcium channel antagonist or a long-acting nitrate if needed. If the combination of two drugs fails to achieve an acceptable symptomatic response, revascularisation should be considered.

**Nitrates**

Nitrates act directly on vascular smooth muscle to produce venous and arteriolar dilatation. Several preparations are available,
Fig. 16.58 A myocardial perfusion scan showing reversible anterior myocardial ischaemia. The resting 12-lead ECG shows some minor T-wave changes in the inferolateral leads but is otherwise normal. After 3 minutes’ exercise on a treadmill, there is marked planar ST depression in leads V4 and V5 (right-hand offset). Subsequent coronary angiography revealed critical three-vessel coronary artery disease.

(GTN = glyceryl trinitrate)

as shown in Box 16.43. They help angina by lowering preload and afterload, which reduces myocardial oxygen demand, and by increasing myocardial oxygen supply through coronary vasodilatation. Sublingual GTN, administered from a metered-dose aerosol (400 μg per spray) or as a tablet (300 or 500 μg), is indicated for acute attacks and will usually relieve an attack in 2–3 minutes. Patients should also be encouraged to use the drug prophylactically before taking exercise that is likely to provoke symptoms. Sublingual GTN has a short duration of action and side-effects include headache, symptomatic hypotension and, rarely, syncope. A more prolonged therapeutic effect can be achieved by giving GTN transcutaneously as a patch (5–10 mg daily) or as a slow-release buccal tablet (1–5 mg 4 times daily). Isosorbide dinitrate (10–20 mg 3 times daily) and isosorbide mononitrate (20–60 mg once or twice daily) can be given by mouth, unlike GTN, which undergoes extensive metabolism in the liver. Headache is common with oral nitrates but tends to diminish if the patient perseveres with the treatment. Continuous nitrate therapy can cause pharmacological tolerance but this can be avoided by a 6–8-hour nitrate-free period, best achieved at night when the patient is inactive. If nocturnal angina is a predominant symptom, long-acting nitrates can be given at the end of the day.

**Beta-blockers**

These lower myocardial oxygen demand by reducing heart rate, BP and myocardial contractility, but they may provoke bronchospasm in patients with asthma. The properties and side-effects of β-blockers are discussed on page 500. In theory, non-selective β-blockers may aggravate coronary vasospasm by blocking coronary artery β2-adrenoceptors, and so a once-daily cardioselective preparation such as slow-release metoprolol (50–200 mg daily) or bisoprolol (5–15 mg daily) is preferable. Beta-blockers should not be withdrawn abruptly, as rebound effects may precipitate dangerous arrhythmias, worsening angina or MI. This is known as the β-blocker withdrawal syndrome.

**Calcium channel antagonists**

These drugs lower myocardial oxygen demand by reducing BP and myocardial contractility. Since dihydropyridine calcium antagonists, such as nifedipine and amldipine, may cause a reflex tachycardia, it is best to use them in combination with a β-blocker. In contrast, verapamil and diltiazem can be used as monotherapy because they slow SA node firing, inhibit conduction through the AV node and tend to cause bradycardia. They are particularly useful when β-blockers are contraindicated. Calcium channel antagonists reduce myocardial contractility and must be used with care in patients with poor LV function, since they can
agonistic use of stents in appropriate vessels reduces and helps to maximise and maintain dilatation of a stenosed vessel. The routine use of stents in appropriate vessels reduces and helps to maximise and maintain dilatation of a stenosed vessel.

Coronary artery bypass grafting

The internal mammary arteries, radial arteries or reversed segments of the patient’s own saphenous vein can be used. The internal mammary arteries, radial arteries or reversed segments of the patient’s own saphenous vein can be used.

Non-pharmacological treatments

Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) involves passing a fine guidewire across a coronary stenosis under radiographic control and using it to position a balloon, which is then inflated to dilate the stenosis (Fig. 16.59). This can be combined with deployment of a coronary stent, which is a piece of metallic ‘scaffolding’ that can be impregnated with drugs with antiproliferative properties and that helps to maximise and maintain dilatation of a stenosed vessel. The routine use of stents in appropriate vessels reduces both acute complications and the incidence of clinically important restenosis (Fig. 16.60).

Treatment with PCI often provides excellent symptom control but does not improve survival in patients with chronic stable angina. It is mainly used in single- or two-vessel disease. Stenoses in bypass grafts can be dilated, as well as those in the native coronary arteries. The technique is often used to provide palliative therapy for patients with recurrent angina after coronary artery bypass grafting.

The main acute complications of PCI are occlusion of the target vessel or a side branch by thrombus or a loose flap of intima (coronary artery dissection), and consequent myocardial damage. This occurs in about 2–5% of procedures and can often be corrected by deploying a stent, although emergency coronary artery bypass grafting may occasionally be required if stenting is unsuccessful. Minor myocardial damage, as indicated by elevation of sensitive intracellular markers (p. 497), occurs in up to 10% of cases. The main long-term complication of PCI is restenosis, in up to one-third of cases. This is due to a combination of elastic recoil and smooth muscle proliferation and tends to occur within 3 months. Stenting substantially reduces the risk of restenosis, probably because it allows the operator to achieve more complete dilatation. Drug-eluting stents reduce this risk further by allowing an antiproliferative drug, such as sirolimus or paclitaxel, to elute slowly from the coating and prevent neo-intimal hyperplasia and in-stent restenosis. These are especially indicated in diabetic patients, or in patients with long or calcific lesions, or small target-vessel diameter. Recurrent angina (affecting up to 5–10% of patients receiving an intracoronary stent at 6 months) may require further PCI or bypass grafting.

The risk of complications and the likely success of the procedure are closely related to the morphology of the stenoses, the experience of the operator and the presence of important comorbidity, such as diabetes and peripheral arterial disease. A good outcome is less likely if the target lesion is complex, long, eccentric or calcified, lies on a bend or within a tortuous vessel, involves a branch or contains thrombus.

Adjunctive therapy with a potent platelet inhibitor such as the P2Y12 receptor antagonists (clopidogrel, prasugrel or ticagrelor) in combination with aspirin and heparin improves the outcome following PCI.

Coronary artery bypass grafting

The internal mammary arteries, radial arteries or reversed segments of the patient’s own saphenous vein can be used to bypass coronary artery stenoses (Fig. 16.61). This usually involves major surgery under cardiopulmonary bypass but, in some cases, grafts can be applied to the beating heart: ‘off-pump’ surgery. The operative mortality is approximately 1.5% but risks are higher in elderly patients, those with poor left ventricular function and those with significant comorbidity, such as renal failure. Approximately 90% of patients are free of angina 1 year after coronary artery bypass grafting (CABG), but fewer than 60% of patients are asymptomatic after 5 or more years. Early post-operative angina is usually due to graft failure arising from technical problems during the operation, or poor ‘run-off’ due

to disease in the distal native coronary vessels. Late recurrence of angina may be caused by progressive disease in the native coronary arteries or graft degeneration. Fewer than 50% of vein grafts are patent 10 years after surgery. Arterial grafts have a much better long-term patency rate, however, with more than 80% of internal mammary artery grafts patent at 10 years. This has led many surgeons to consider total arterial revascularisation during CABG surgery. Aspirin (75–150 mg daily) and clopidogrel (75 mg daily) both improve graft patency, and one or the other should be prescribed indefinitely. Intensive lipid-lowering therapy slows the progression of disease in the native coronary arteries and bypass grafts, and reduces clinical cardiovascular events. There is substantial excess cardiovascular morbidity and mortality in patients who continue to smoke after bypass grafting. Persistent smokers are twice as likely to die in the 10 years following surgery than those who give up at surgery.

Survival is improved by CABG in symptomatic patients with left main stem stenosis or three-vessel coronary disease when the LAD, CX and right coronary arteries are involved, or two-vessel disease involving the proximal LAD coronary artery. Improvement in survival is most marked in those with impaired left ventricular function or positive stress testing prior to surgery and in those who have undergone left internal mammary artery grafting.

Neurological complications are common, with a 1–5% risk of perioperative stroke. Between 30% and 80% of patients develop
short-term cognitive impairment that typically resolves within 6 months. There are also reports of long-term cognitive decline that may be evident in more than 30% of patients at 5 years. PCI and CAGB are compared in Box 16.45.

**Prognosis**

The prognosis of CAD is related to the number of diseased vessels and the degree of left ventricular dysfunction. A patient with single-vessel disease and good left ventricular function has a 5-year survival of more than 90%. In contrast, a patient with severe left ventricular dysfunction and extensive three-vessel disease has a 5-year survival of less than 30% unless revascularisation is performed. Symptoms are a poor guide to prognosis, since spontaneous improvement in angina due to the development of collateral vessels is common. Nevertheless, the 5-year mortality of patients with severe angina (CCS angina scale III or IV, see Box 16.40) is nearly double that of patients with mild symptoms.

### Acute coronary syndrome

Acute coronary syndrome is a term that encompasses both unstable angina and myocardial infarction. Unstable angina is characterised by new-onset or rapidly worsening angina (crescendo angina), angina on minimal exertion or angina at rest in the absence of myocardial damage. Myocardial infarction differs from unstable angina, since there is evidence of myocardial necrosis. The term acute myocardial infarction (MI) should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischaemia. Under these conditions, any one of the criteria shown in Box 16.47 fulfils the criteria for the diagnosis of an acute MI. The diagnosis of a previous MI can be made when any one of the features shown in Box 16.48 is present.

Acute coronary syndrome may present as a new phenomenon in patients with no previous history of heart disease or against a background of chronic stable angina. Approximately 12% of patients with acute coronary syndrome die within 1 month and 20% within 6 months of the index event. The risk markers that are indicative of an adverse prognosis include recurrent ischaemia, extensive ECG changes at rest or during pain, raised troponin I or T levels, arrhythmias and haemodynamic complications.

#### 16.46 Angina in old age

- **Incidence**: coronary artery disease increases in old age and affects women almost as often as men.
- **Comorbid conditions**: anaemia and thyroid disease are common and may worsen angina.
- **Calcific aortic stenosis**: common and should be sought in all older people with angina.
- **Atypical presentations**: when myocardial ischaemia occurs, age-related changes in myocardial compliance and diastolic relaxation can cause the presentation to be with symptoms of heart failure, such as breathlessness, rather than with chest discomfort.
- **Angioplasty and coronary artery bypass surgery**: provide symptomatic relief, although with increased procedure-related morbidity and mortality. Outcome is determined by the number of diseased vessels, severity of cardiac dysfunction and the number of concomitant diseases, as much as by age itself.

#### 16.47 Criteria for diagnosis of an acute myocardial infarction (MI)

- Detection of a rise and/or fall of cardiac biomarker values (preferably cardiac troponin (cTn)), with at least one value above the 99th centile upper reference limit (URL) and with at least one of the following:
  1. Symptoms of ischaemia
  2. New or presumed new significant ST segment–T wave (ST–T) changes or new left bundle branch block (LBBB)
  3. Development of pathological Q waves in the ECG
  4. Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
  5. Identification of an intracoronary thrombus by angiography or postmortem
- Cardiac death with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes or new LBBB, but death occurred before cardiac biomarkers were obtained, or before cardiac biomarker values would be increased
- Percutaneous coronary intervention (PCI)-related MI is arbitrarily defined by elevation of cTn values (>5×99th centile URL) in patients with normal baseline values (<99th centile URL) or a rise of cTn values >20% if the baseline values are elevated and are stable or falling. In addition, either (i) symptoms suggestive of myocardial ischaemia, or (ii) new ischaemic ECG changes, or (iii) angiographic findings consistent with a procedural complication, or (iv) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality are required
- Sudden thrombosis associated with MI when detected by coronary angiography or postmortem in the setting of myocardial ischaemia and with a rise and/or fall of cardiac biomarker values with at least one value above the 99th centile URL
- Coronary artery bypass grafting (CABG)-related MI is arbitrarily defined by elevation of cardiac biomarker values (>10×99th centile URL) in patients with normal baseline cTn values (<99th centile URL). In addition, either (i) new pathological Q waves or new LBBB, or (ii) angiographic documented new graft or new native coronary artery occlusion, or (iii) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality is required

(hypotension, mitral regurgitation) during episodes of ischaemia. Careful assessment and risk stratification are important because these guide the use of more complex pharmacological and interventional treatments (Figs 16.62 and 16.70), which can improve outcome (p. 501).

**Pathogenesis**

Acute coronary syndrome almost always occurs in patients who have atherosclerosis. The culprit lesion that precipitates the acute event is usually a complex ulcerated or fissured atheromatous plaque with adherent platelet-rich thrombus and local coronary artery spasm (see Fig. 16.54). These vascular changes during an acute coronary syndrome are dynamic, such that the degree of obstruction may either increase, leading to complete vessel occlusion, or regress due to the effects of platelet disaggregation and endogenous fibrinolysis. In acute MI, occlusive thrombus is almost always present at the site of rupture or erosion of an atheromatous plaque. The thrombus may undergo spontaneous lysis over the course of the next few days, although, by this time, irreversible myocardial damage has occurred. Without treatment, the artery responsible for the MI remains permanently occluded in 20–30% of patients. Since the process of infarction progresses over several hours (Fig. 16.63), most patients present when it is still possible to salvage myocardium and improve outcome.

**Clinical features**

The differential diagnosis of acute coronary syndrome is wide and includes most causes of central chest pain or collapse (p. 176). Chest pain at rest is the cardinal symptom but breathlessness, vomiting and collapse are also common features (Box 16.49).

### 16.48 Criteria for diagnosis of a prior myocardial infarction

- Pathological Q waves with or without symptoms in the absence of non-ischaemic causes
- Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract, in the absence of a non-ischaemic cause
- Pathological findings of a prior myocardial infarction

### Examples

A patient has Killip class II, SBP of 99 mmHg, heart rate of 100 beats/min, is 65 years of age, has a serum creatinine level of 76 μmol/L, did not have a cardiac arrest at admission but did have ST-segment deviation and elevated enzyme levels. His score would be: 20 + 53 + 15 + 58 + 7 + 30 + 1 = 195. This gives about a 16% risk of having an in-hospital death.

Similarly, a patient with Killip class I, SBP of 80 mmHg, heart rate of 60 beats/min, who is 55 years of age, has a serum creatinine level of 30 μmol/L, and no risk factors would have the following score: 0 + 58 + 3 + 41 + 1 = 103. This gives about a 0.9% risk of having an in-hospital death.

**Fig. 16.62** Risk stratification in the acute coronary syndrome: the GRACE score. Killip class refers to a categorisation of the severity of heart failure based on easily obtained clinical signs. The main clinical features are as follows: class I = no heart failure; class II = crackles audible halfway up the chest; class III = crackles heard in all the lung fields; class IV = cardiogenic shock. To convert creatinine in μmol/L to mg/dL, divide by 88.4. (SBP = systolic blood pressure) From Scottish Intercollegiate Guidelines Network (SIGN) Guideline no. 93 – Acute coronary syndromes; February 2007.
The pain occurs in the same sites as angina but is usually more severe and lasts longer; it is often described as a tightness, heaviness or constriction in the chest. In acute MI the pain can be excruciating, and the patient’s expression and pallor may vividly convey the seriousness of the situation. Most patients are breathless and, in some, this is the only symptom. Painless or ‘silent’ MI may also occur and is particularly common in older patients or those with diabetes mellitus. If syncope occurs, it is usually caused by an arrhythmia or profound hypotension. Vomiting and sinus bradycardia are often due to vagal stimulation and are particularly common in patients with inferior MI. Nausea and vomiting may also be caused or aggravated by opiates given for pain relief. Sometimes infarction occurs in the absence of physical signs. Sudden death, from ventricular fibrillation or asystole, may occur immediately and often within the first hour. If the patient survives this most critical stage, the liability to dangerous arrhythmias remains, but diminishes as each hour goes by. It is vital that patients know not to delay calling for help if symptoms occur. Complications may occur in all forms of acute coronary syndrome but have become less frequent in the modern era of immediate or early coronary revascularisation. Specific complications of acute coronary syndromes and their management are discussed below.

### 16.50 Common arrhythmias in acute coronary syndrome

- Ventricular fibrillation
- Ventricular tachycardia
- Accelerated idioventricular rhythm
- Ventricular ectopics
- Atrial fibrillation
- Atrial tachycardia
- Sinus bradycardia (particularly after inferior myocardial infarction)
- Atrioventricular block

### Arrhythmias

Arrhythmias are common in patients with acute coronary syndrome (Box 16.50) but are often transient and of no haemodynamic or prognostic importance. The risk of arrhythmia can be minimised by adequate pain relief, rest and the correction of hypokalaemia. VF occurs in 5–10% of patients who reach hospital and is thought to be the major cause of death in those who die before receiving medical attention. Prompt defibrillation restores sinus rhythm and is life-saving. The prognosis of patients with early VF (within the first 48 hours) who are successfully and promptly resuscitated is identical to that of patients who do not suffer VF. The presence of ventricular arrhythmias during the convalescent phase of acute coronary syndrome may be a marker of poor ventricular function and may herald sudden death. Selected patients may benefit from electrophysiological testing and specific anti-arrhythmic therapy (including ICDs, p. 483). AF is a common but frequently transient arrhythmia, and usually does not require emergency treatment. However, if it causes a rapid ventricular rate with hypotension or circulatory collapse, prompt cardioversion is essential. In other situations, digoxin or a β-blocker is usually the treatment of choice. AF may be a feature of impending or overt left ventricular failure, and therapy may be ineffective if heart failure is not recognised and treated appropriately. Anticoagulation is required if AF persists. Bradycardia may occur but does not require treatment unless there is hypotension or haemodynamic deterioration, in which case atropine (0.6–1.2 mg IV) may be given. Inferior MI may be complicated by AV block, which is usually temporary and often resolves following reperfusion therapy. If there is clinical deterioration due to second-degree or complete AV block, a temporary pacemaker should be considered. AV block complicating anterior infarction is more serious because asystole may suddenly supervene. A prophylactic temporary pacemaker should be inserted in these patients (p. 482).

### Recurrent angina

Patients who develop recurrent angina at rest or on minimal exertion following an acute coronary syndrome are at high risk and should be considered for prompt coronary angiography with a view to revascularisation. Patients with dynamic ECG changes and ongoing pain should be treated with intravenous glycoprotein IIb/IIIa receptor antagonists. Patients with resistant pain or marked haemodynamic changes should be considered for intra-aortic balloon counterpulsation and emergency coronary revascularisation. Post-infarct angina occurs in up to 50% of patients treated with thrombolysis. Most patients have a residual stenosis in the infarct-related vessel, despite successful thrombolysis, and this may cause angina if there is still viable myocardium downstream. For this reason, all patients who have received successful thrombolysis should be considered for early (within the first 6–24 hours) coronary angiography with a view to coronary revascularisation.
Acute heart failure

Acute heart failure usually reflects extensive myocardial damage and is associated with a poor prognosis. All the other complications of MI are more likely to occur when acute heart failure is present. The assessment and management of heart failure is discussed in more detail on pages 463 and 465.

Pericarditis

This only occurs following infarction and is particularly common on the second and third days. The patient may recognise that a different pain has developed, even though it is at the same site, and that it is positional and tends to be worse or sometimes present only on inspiration. A pericardial rub may be audible. Opiate-based analgesia should be used. Non-steroidal (NSAIDs) and steroidal anti-inflammatory drugs may increase the risk of aneurysm formation and myocardial rupture in the early recovery period, and should be avoided.

Dressler’s syndrome

This syndrome is characterised by persistent fever, pericarditis and pleuritis, and is probably due to autoimmunity. The symptoms tend to occur a few weeks or even months after MI and often subside after a few days. If the symptoms are prolonged or severe, treatment with high-dose aspirin, NSAIDs or even glucocorticoids may be required.

Papillary muscle rupture

This typically presents with acute pulmonary oedema and shock due to the sudden onset of severe mitral regurgitation. Examination usually reveals a pansystolic murmur and third heart sound but the murmur may be quiet or absent in patients with severe mitral regurgitation. The diagnosis is confirmed by echocardiography, and emergency valve replacement may be necessary. Lesser degrees of mitral regurgitation due to papillary muscle dysfunction are common and may be transient.

Ventricular septum rupture

This usually presents with sudden haemodynamic deterioration accompanied by a new and loud pansystolic murmur radiating to the right sternal border, which may be difficult to distinguish from acute mitral regurgitation. Rupture of the intraventricular septum causes left-to-right shunting through a ventricular septal defect, which tends to cause acute right heart failure rather than pulmonary oedema. Doppler echocardiography and right heart catheterisation will confirm the diagnosis. Treatment is by emergency surgical repair; without this, the condition is usually fatal.

Ventricular rupture

Rupture of the ventricle may lead to cardiac tamponade and is usually fatal (p. 544), although it is occasionally possible to support a patient with an incomplete rupture until emergency surgery can be performed.

Embolism

Thrombus often forms on the endocardial surface of freshly infarcted myocardium. This can lead to systemic embolism and occasionally causes a stroke or ischaemic limb. Venous thrombosis and pulmonary embolism may occur but have become less common with the use of prophylactic anticoagulants and early mobilisation.

Ventricular remodelling

This is a potential complication of an acute transmural MI due to thinning and stretching of the infarcted segment. This leads to an increase in wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling).

Fig. 16.64 Infarct expansion and ventricular remodelling. Full-thickness myocardial infarction causes thinning and stretching of the infarcted segment (infarct expansion), which leads to increased wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling).

Ventricular aneurysm

Ventricular aneurysm develops in approximately 10% of patients with MI and is particularly common when there is persistent occlusion of the infarct-related vessel. Heart failure, ventricular arrhythmias, mural thrombus and systemic embolism are all recognised complications of aneurysm formation. Other features include a paradoxical impulse on the chest wall, persistent ST elevation on the ECG, and sometimes an unusual bulge from the cardiac silhouette on the chest X-ray. Echocardiography is diagnostic. Surgical removal of a left ventricular aneurysm carries a high morbidity and mortality but is sometimes necessary.

Investigations

Electrocardiogram

The standard 12-lead ECG is central to confirming the diagnosis but may be difficult to interpret if there is bundle branch block or previous MI. The initial ECG may be normal or non-diagnostic in one-third of cases. Repeated ECGs are important, especially where the diagnosis is uncertain or the patient has recurrent or persistent symptoms. The earliest ECG change is usually ST-segment deviation. With proximal occlusion of a major coronary artery, ST-segment elevation (or new bundle branch block) is seen initially, with later diminution in the size of the R wave and, in transmural (full-thickness) infarction, development of a Q wave. Subsequently, the T wave becomes inverted because of a change in ventricular repolarisation; this change persists after the ST segment has returned to normal. These sequential features (Fig. 16.65) are sufficiently reliable for the approximate age of the infarct to be deduced.

In non-ST segment elevation acute coronary syndrome, there is partial occlusion of a major vessel or complete occlusion of...
Coronary artery disease

Fig. 16.65 The serial evolution of ECG changes in transmural myocardial infarction. [A] Normal ECG complex. [B] Acute ST elevation (‘the current of injury’). [C] Progressive loss of the R wave, developing Q wave, resolution of the ST elevation and terminal T-wave inversion. [D] Deep Q wave and T-wave inversion. [E] Old or established infarct pattern; the Q wave tends to persist but the T-wave changes become less marked. The rate of evolution is very variable but, in general, stage B appears within minutes, stage C within hours, stage D within days and stage E after several weeks or months. This should be compared with the 12-lead ECGs in Figures 16.66–16.68.

Cardiac biomarkers

Serial measurements of serum troponin should be taken. In unstable angina, there is no detectable rise in troponin and the diagnosis is made on the basis of the clinical history and ECG changes. In contrast, MI causes a rise in plasma troponin T and I concentrations and other cardiac muscle enzymes (p. 450; Fig. 16.69 and see Box 16.47). Levels of troponins T and I increase within 3–6 hours, peak at about 36 hours and remain elevated for up to 2 weeks. A full blood count may reveal the presence of a leucocytosis, which reaches a peak on the first day. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also elevated. Lipids should be measured within 24 hours of presentation because there is often a transient fall in cholesterol in the 3 months following infarction.

Radiography

A chest X-ray should be performed since this may demonstrate pulmonary oedema that is not evident on clinical examination (see Fig. 16.27, p. 464). The heart size is often normal but

Fig. 16.66 Recent anterior non-ST elevation (subendocardial) myocardial infarction. This ECG demonstrates deep symmetrical T-wave inversion, together with a reduction in the height of the R wave in leads V1, V3, V4 and V6.

A minor vessel, causing unstable angina or partial-thickness (subendocardial) MI. This is usually associated with ST-segment depression and T-wave changes. In the presence of infarction, this may be accompanied by some loss of R waves in the absence of Q waves (Fig. 16.66).

The ECG changes are best seen in the leads that ‘face’ the ischaemic or infarcted area. When there has been anteroseptal infarction, abnormalities are found in one or more leads from V1 to V4, while anterolateral infarction produces changes from V4 to V6, in aVL and in lead I. Inferior infarction is best shown in leads II, III and aVF, while, at the same time, leads I, aVL and the anterior chest leads may show ‘reciprocal’ changes of ST depression (Figs 16.67 and 16.68). Infarction of the posterior wall of the LV does not cause ST elevation or Q waves in the standard leads, but can be diagnosed by the presence of reciprocal changes (ST depression and a tall R wave in leads V1–V4). Some infarctions (especially inferior) also involve the RV. This may be identified by recording from additional leads placed over the right precordium.

Cardiac biomarkers

Serial measurements of serum troponin should be taken. In unstable angina, there is no detectable rise in troponin and the diagnosis is made on the basis of the clinical history and ECG changes. In contrast, MI causes a rise in plasma troponin T and I concentrations and other cardiac muscle enzymes (p. 450; Fig. 16.69 and see Box 16.47). Levels of troponins T and I increase within 3–6 hours, peak at about 36 hours and remain elevated for up to 2 weeks. A full blood count may reveal the presence of a leucocytosis, which reaches a peak on the first day. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also elevated. Lipids should be measured within 24 hours of presentation because there is often a transient fall in cholesterol in the 3 months following infarction.

Radiography

A chest X-ray should be performed since this may demonstrate pulmonary oedema that is not evident on clinical examination (see Fig. 16.27, p. 464). The heart size is often normal but
event, including those who fail to settle on medical therapy, those with extensive ECG changes, those with an elevated plasma troponin and those with severe pre-existing stable angina (Fig. 16.70). This often reveals disease that is amenable to PCI or urgent CABG (see below).

Management

All patients with suspected acute coronary syndrome should be admitted urgently to hospital because there is a significant risk of death or recurrent myocardial ischaemia during the early unstable phase. Appropriate medical therapy can reduce the incidence of these complications by at least 60%. The key elements of immediate in-hospital management are shown in Figure 16.70. Patients should ideally be managed in a dedicated cardiac unit, where the necessary expertise, monitoring and resuscitation facilities are available. Clinical risk factor analysis using tools such as the GRACE score (see Fig. 16.62) should be performed to identify patients that should be selected for intensive therapy, and specifically early inpatient coronary angiography (thresholds vary, but a score of 140 points or more indicates early intervention). If there are no complications and risk factor analysis shows that angiography is not required, the patient can be mobilised from the second day and discharged after 2–3 days. Low-risk patients without spontaneous angina should undergo an exercise tolerance test approximately 4 weeks after the acute coronary syndrome. This will help to identify those individuals with residual myocardial ischaemia who require further investigation, and may help to boost the confidence of the remainder. Management of the acute event is discussed below and the principles of long-term management are summarised in Box 16.51.

Analgesia

Adequate analgesia is essential, not only to relieve distress but also to lower adrenergic drive and thereby reduce vascular resistance, BP, infarct size and susceptibility to ventricular arrhythmias. Intravenous opiates (initially, morphine sulphate 5–10 mg or diamorphine 2.5–5 mg) and antiemetics (initially, metoclopramide 10 mg) should be administered, and titrated by giving repeated small aliquots until the patient is comfortable. Intramuscular injections should be avoided because the clinical effect may be delayed by poor skeletal muscle perfusion, and a painful haematoma may form following thrombolytic or antithrombotic therapy.
Immediate reperfusion therapy with PCI (see Fig. 16.60) is indicated when the ECG shows new bundle branch block or characteristic ST-segment elevation in two contiguous leads of 1 mm or more in the limb leads or 2 mm or more in the chest leads. This procedure has revolutionised the outcomes for these patients and is the treatment of choice for those presenting within 12 hours of symptom onset (Fig. 16.70). If PCI cannot be performed within 120 minutes for any reason, and thrombolysis is contraindicated, the procedure should be performed as soon as practically possible. Patients should be considered for PCI within the first 24 hours, even if they have reperfused spontaneously or with thrombolytic therapy. Coronary artery patency is restored in over 95% of patients undergoing PCI. The procedure preserves left ventricular function with a marked reduction in the progression to heart failure, more than halves rates of recurrent MI and dramatically improves mortality with more than 95% 1-year survival rates in clinical trials. Successful therapy is also associated with rapid pain relief, resolution of acute ST elevation and occasional transient arrhythmias.
Selected medium- to high-risk patients do benefit from in-hospital coronary angiography and coronary revascularisation but this does not need to take place in the first 12 hours unless there are high-risk features, such as ongoing chest pain or ECG changes. Reperfusion therapy with PCI confers no immediate mortality benefit in patients with non-ST segment elevation acute coronary syndrome.

**Thrombolytic therapy**

If primary PCI cannot be achieved in a timely manner (see Fig. 16.70), thrombolytic therapy should be administered. Although the survival advantage is not as good as primary PCI, mortality is reduced and this is maintained for at least 10 years. The benefit of thrombolytic therapy is greatest in those patients who receive treatment within the first 12 hours and especially the first 2 hours. Modern thrombolytic agents, such as tenecteplase (TNK) and reteplase (rPA), are analogues of human tissue plasminogen activator and can be given as an intravenous bolus, assisting prompt treatment in the emergency department or in the pre-hospital setting. The major hazard of thrombolytic therapy is bleeding. Cerebral haemorrhage causes 4 extra strokes per 1000 patients treated, and the incidence of other major bleeds is between 0.5% and 1%. Accordingly, the treatment should be withheld if there is a significant risk of serious bleeding (Box 16.52). For some patients, thrombolytic therapy is contraindicated or fails to achieve coronary arterial reperfusion (Fig. 16.70). Emergency PCI may then be considered, particularly where there is evidence of cardiogenic shock. Even where thrombosis successfully achieves reperfusion, PCI should be considered within 24 hours to prevent recurrent infarction and improve outcome.

**Antithrombotic therapy**

Oral administration of 75–325 mg aspirin daily improves survival, with a 25% relative risk reduction in mortality. The first tablet (300 mg) should be given orally within the first 12 hours and therapy should be continued indefinitely if there are no side-effects. A P2Y12 receptor antagonist should be given in combination with aspirin for up to 12 months. The strongest evidence is for ticagrelor (180 mg, followed by 90 mg twice daily) but prasugrel (60 mg, followed by 10 mg daily) is an alternative. If the patient is intolerant of aspirin, clopidogrel is a suitable alternative (300 mg, followed by 75 mg daily). Glycoprotein IIb/IIIa receptor antagonists, such as tirofiban and abciximab, block the final common pathway of platelet aggregation and are potent inhibitors of platelet-rich thrombus formation. They are of particular benefit in high-risk patients with acute coronary syndromes who undergo PCI, especially those with a high thrombus burden at angiography or who have received inadequate prior antiplatelet therapy. These intravenous agents are administered in addition to oral aspirin and a P2Y12 inhibitor such as clopidogrel. Anticoagulation further reduces the risk of thromboembolic complications, and prevents re-infarction in the absence of reperfusion therapy or after successful thrombolysis. Anticoagulation can be achieved using unfractionated heparin, fractioned (low-molecular-weight) heparin or a pentasaccharide such as fondaparinux (2.5 mg daily). Comparative clinical trials show that the pentasaccharides have the best safety and efficacy profile but low-molecular-weight heparin, such as subcutaneous enoxaparin (1 mg/kg twice daily), is a reasonable alternative. Anticoagulation should be continued for 8 days or until discharge from hospital or coronary revascularisation has been completed. A period of treatment with warfarin should be considered if there is persistent AF or evidence of extensive anterior infarction with mural thrombus because these patients are at increased risk of systemic thromboembolism.

**Anti-anginal therapy**

Sublingual glyceryl trinitrate (300–500 μg) is a valuable first-aid measure in unstable angina or threatened infarction, and intravenous nitrates (glyceryl trinitrate 0.6–1.2 mg/hr or isosorbide dinitrate 1–2 mg/hr) are useful for the treatment of left ventricular failure and the relief of recurrent or persistent ischaemic pain. Intravenous β-blockers (atenolol 5–10 mg or metoprolol 5–15 mg given over 5 mins) relieve pain, reduce arrhythmias and improve short-term mortality in patients who present within 12 hours of the onset of symptoms (Fig. 16.70). However, they should be avoided if there is heart failure (pulmonary oedema), hypotension (systolic BP <105 mmHg) or bradycardia (heart rate <65/min). Nifedipine or amiodipine can be added to the β-blocker if there is persistent chest discomfort but these drugs may cause tachycardia if used alone. Verapamil and diltiazem should be used if a β-blocker is contraindicated. In the longer term, treatment with an oral β-blocker reduces long-term mortality by approximately 25% among the survivors of an acute MI. Patients with heart failure, irreversible COPD or peripheral arterial disease derive similar, if not greater, secondary preventative benefits from β-blocker therapy and should receive maintenance therapy unless it is poorly tolerated. Unfortunately, a minority of patients do not tolerate β-blockers because of bradycardia, AV block, hypotension or asthma.

**Renin–angiotensin blockade**

Long-term treatment with ACE inhibitors such as enalapril (10 mg twice daily) or ramipril (2.5–5 mg twice daily) can counteract ventricular remodelling, prevent the onset of heart failure, improve survival, reduce recurrent MI and avoid rehospitalisation. The

---

**16.53 Myocardial infarction in old age**

- **Atypical presentation**: often with anorexia, fatigue, weakness, delirium or falls rather than chest pain.
- **Case fatality**: rises steeply. Hospital mortality exceeds 25% in those over 75 years old, which is five times greater than that seen in those aged less than 55 years.
- **Survival benefit of treatments**: not influenced by age. The absolute benefit of evidence-based treatments may therefore be greatest in older people.
- **Hazards of treatments**: rise with age (for example, increased risk of intracerebral bleeding after thrombolysis) and are due partly to increased comorbidity.
- **Quality of evidence**: older patients, particularly those with significant comorbidity, were under-represented in many of the randomised controlled clinical trials that helped to establish the treatment of myocardial infarction. The balance of risk and benefit for many treatments, such as thrombolysis and primary percutaneous transluminal coronary angiography, in frail older people is uncertain.
benefits are greatest in those with overt heart failure (clinical or radiological) but extend to patients with asymptomatic left ventricular dysfunction and those with preserved left ventricular function. They should therefore be considered in all patients with acute coronary syndrome. Caution must be exercised in hypovolaemic or hypotensive patients because ACE inhibition may exacerbate hypotension and impair coronary perfusion. In patients intolerant of ACE inhibitors, ARBs such as valsartan (40–160 mg twice daily) or candesartan (4–16 mg daily) are alternatives and are better tolerated.

Mineralocorticoid receptor antagonists

Patients with acute MI and left ventricular dysfunction (ejection fraction <35%) and either pulmonary oedema or diabetes mellitus further benefit from additional mineralocorticoid receptor antagonism (eplerenone 25–50 mg daily, or spironolactone 25–50 mg daily).

Lipid-lowering therapy

The benefits of lowering serum cholesterol following acute coronary syndrome have been demonstrated in several large-scale randomised trials. All patients should receive therapy with HMG CoA reductase enzyme inhibitors (statins) after acute coronary syndrome, irrespective of serum cholesterol concentrations. Patients with serum LDL cholesterol concentrations above 3.2 mmol/L (approximately 120 mg/dL) benefit from more intensive therapy, such as atorvastatin (80 mg daily). Other agents, such as ezetimibe, fibrates, anion exchange resins and injectable PCSK9 inhibitors, may be used in cases where total cholesterol or LDL cholesterol cannot be lowered adequately using statins alone.

Smoking cessation

The 5-year mortality of patients who continue to smoke cigarettes is double that of those who quit smoking at the time of their acute coronary syndrome. Giving up smoking is the single most effective contribution a patient can make to his or her future. The success of smoking cessation can be increased by supportive advice and pharmacological therapy (p. 94).

Diet and exercise

Maintaining an ideal body weight, eating a Mediterranean-style diet, taking regular exercise, and achieving good control of hypertension and diabetes mellitus may all improve the long-term outlook.

Rehabilitation

The necrotic muscle of an acute myocardial infarct takes 4–6 weeks to be replaced with fibrous tissue and it is conventional to restrict physical activities during this period. When there are no complications, the patient can mobilise on the second day, return home in 2–3 days and gradually increase activity, with the aim of returning to work in 4 weeks. The majority of patients may resume driving after 1–4 weeks, although, in most countries, drivers of heavy goods and public service vehicles require special assessment before returning to work. Emotional problems, such as denial, anxiety and depression, are common and must be addressed. Some patients are severely and even permanently incapacitated as a result of the psychological effects of acute coronary syndrome rather than the physical ones, and all benefit from thoughtful explanation, counselling and reassurance. Many patients mistakenly believe that stress was the cause of their heart attack and may restrict their activity inappropriately. The patient’s spouse or partner will also require emotional support, information and counselling. Formal rehabilitation programmes, based on graded exercise protocols with individual and group counselling, are often very successful and, in some cases, have been shown to improve the long-term outcome.

Implantable defibrillators

ICDs are of benefit in preventing sudden cardiac death in patients who have severe left ventricular impairment (ejection fraction ≤30%) after MI (p. 483).

Prognosis

The prognosis of patients who have survived an acute coronary syndrome is related to the extent of residual myocardial ischaemia, the degree of myocardial damage and the presence of ventricular arrhythmias. In almost one-quarter of all cases of MI, death occurs within a few minutes without medical care. Half the deaths occur within 24 hours of the onset of symptoms and about 40% of all affected patients die within the first month. The prognosis of those who survive to reach hospital is much better, with a 28-day survival of more than 85%. Patients with unstable angina have a mortality of approximately half that of patients with MI. Early death is usually due to an arrhythmia and is independent of the extent of MI. However, late outcomes are determined by the extent of myocardial damage, and unfavourable features include poor left ventricular function, AV block and persistent ventricular arrhythmias. The prognosis is worse for anterior than for inferior infarcts. Bundle branch block and high cardiac marker levels both indicate extensive myocardial damage. Old age, depression and social isolation are also associated with a higher mortality. Of those who survive an acute attack, more than 80% live for a further year, about 75% for 5 years, 50% for 10 years and 25% for 20 years.

Non-cardiac surgery in patients with heart disease

Non-cardiac surgery, particularly major vascular, abdominal or thoracic surgery, can precipitate serious perioperative cardiac complications, such as MI and death, in patients with CAD and other forms of heart disease. Careful pre-operative cardiac assessment may help to determine the balance of benefit versus risk on an individual basis, and identify measures that minimise the operative risk (Box 16.54).

A hypercoagulable state is part of the normal physiological response to surgery, and may promote coronary thrombosis leading to an acute coronary syndrome in the early post-operative period. Patients with a history of recent PCI or acute coronary syndrome are at greatest risk and, whenever possible, elective non-cardiac surgery should be avoided for 3 months after such an event. Where possible, antiplatelet agents, statins and β-blocker therapies should be continued throughout the perioperative period.

### 16.54 Major risk factors for cardiac complications of non-cardiac surgery

- Recent (< 6 months) myocardial infarction or unstable angina
- Severe coronary artery disease: left main stem or three-vessel disease
- Severe stable angina on effort
- Severe left ventricular dysfunction
- Severe valvular heart disease (especially aortic stenosis)
Peripheral arterial disease

Peripheral arterial disease (PAD) has been estimated to affect about 20% of individuals aged 55–75 years in the UK. Only 25% of patients present with symptoms, the most common of which is intermittent claudication (IC). About 1–2% of patients with IC per year progress to a point where amputation and/or revascularisation are required. However, the annual mortality rate of people with IC is about 5%, which is 2–3 times higher than the general population of the same age and gender. The cause of death is typically an MI or stroke, reflecting the fact that IC nearly always occurs in association with widespread atherosclerosis.

Pathogenesis

In developed countries, almost all PAD is due to atherosclerosis and the risk factors are the same as described in patients with CAD. As with CAD, plaque rupture is responsible for the most serious manifestations of PAD, and not infrequently occurs in a plaque that hitherto has been asymptomatic. The clinical manifestations depend on the anatomical site, the presence or absence of a collateral supply, the speed of onset and the mechanism of injury (Box 16.55). Approximately 5–10% of patients with PAD have diabetes but this proportion increases to 30–40% in those with severe limb ischaemia. The mechanism of PAD in diabetes is atheroma affecting the medium-sized to large arteries rather than obstructive microangiopathy and so diabetes is not a contraindication to lower limb revascularisation. Nevertheless, diabetic patients with PAD pose a number of particular problems (Box 16.56).

Clinical features

Symptomatic PAD affects the legs about eight times more commonly than the arms. Several locations may be affected, including the aortoiliac vessels, the femoropopliteal vessels and the infrapopliteal vessels. One or more of these segments may be affected in a variable and asymmetric manner. In the arm, the subclavian artery is the most common site of disease. Peripheral artery disease can present clinically in a variety of ways, as detailed below.

Intermittent claudication

This is the most common presentation of PAD affecting the lower limbs. It is characterised by ischaemic pain affecting the muscles of the leg. The pain is usually felt in the calf because

(TIA = transient ischaemic attack)

the disease most commonly affects the superficial femoral artery, but it may be felt in the thigh or buttock if the iliac arteries are involved. Typically, the pain comes on after walking, often once a specific distance has been covered, and rapidly subsides on resting. Resumption of walking leads to a return of the pain. Most patients describe a cyclical pattern of exacerbation and resolution due to the progression of disease and the subsequent development of collaterals. When PAD affects the upper limbs, arm claudication may occur, although this is uncommon.

Critical limb ischaemia

Critical limb ischaemia (CLI) is defined as rest pain requiring opiate analgesia, and/or ulceration or gangrene that has been present for more than 2 weeks, in the presence of an ankle BP of less than 50 mmHg. The typical progression of symptoms in CLI is summarised in Figure 16.71. Rest pain only, with ankle pressures above 50 mmHg, is known as subcritical limb ischaemia (SCLI). The term severe limb ischaemia (SLI) is used to describe
If there are no contraindications (acute aortic dissection or death/amputation and complete recovery of limb function), vascular surgeon; a few hours can make the difference between acutely ischaemic limbs must be discussed immediately with a vascular surgeon. Pain on squeezing the calf indicates muscle infarction and specific, however, and inconsistently related to its severity. ‘Ps of acute ischaemia’ (Box 16.57). These features are non-specific, however, and inconsistently related to its severity. Pain on squeezing the calf indicates muscle infarction and impending irreversible ischaemia. All patients with suspected acutely ischaemic limbs must be discussed immediately with a vascular surgeon; a few hours can make the difference between death/amputation and complete recovery of limb function. If there are no contraindications (acute aortic dissection or trauma, particularly head injury), an intravenous bolus of heparin (3000–5000 U) should be administered to limit propagation of thrombus and protect the collateral circulation. Distinguishing thrombosis from embolism is frequently difficult but is important because treatment and prognosis are different (Box 16.58).

Acute limb ischaemia

This is most frequently caused by acute thrombotic occlusion of a pre-existing stenotic arterial segment, thromboembolism, and trauma that may be iatrogenic. The typical presentation is with paralysis (inability to wiggle toes/fingers) and paraesthesia (loss of light touch over the dorsum of the foot/hand), the so-called ‘Ps of acute ischaemia’ (Box 16.57). These features are non-specific, however, and inconsistently related to its severity. Pain on squeezing the calf indicates muscle infarction and impending irreversible ischaemia. All patients with suspected acutely ischaemic limbs must be discussed immediately with a vascular surgeon; a few hours can make the difference between death/amputation and complete recovery of limb function. If there are no contraindications (acute aortic dissection or

(ABPI = ankle–brachial pressure index)

**Acute limb ischaemia**

- Pain develops, typically in forefoot, about an hour after patient goes to bed because:
  - beneficial effects of gravity on perfusion are lost
  - patient’s blood pressure and cardiac output fall during sleep

  Severe pain awakens patient

- Pain relieved by hanging limb out of bed. In due course patient has to get up and walk about, with resulting loss of sleep

  Patient takes to sleeping in chair, leading to dependent oedema. Interstitial tissue pressure is increased so arterial perfusion is further reduced. Vicious circle of increasing pain and sleep loss

  Trivial injury fails to heal, and entry of bacteria leads to infection and increase in metabolic demands of foot. Rapid development of ulcers and gangrene

Fig. 16.71 Progressive night pain and the development of tissue loss.
small emboli lodging in digital arteries. This may be confused with Raynaud’s phenomenon (p. 1035) but the symptoms of athroembolism are typically unilateral rather than bilateral as in Raynaud’s.

Subclavian steal
This can be a feature of PAD affecting the upper limbs. The presentation is with dizziness, cortical blindness and/or collapse, which occurs when the arm is used and is thought to be caused by diversion (or steal) of blood from the brain to the limbs via the vertebral artery.

Investigations
The presence and severity of ischaemia can usually be determined by clinical examination (Box 16.59) and measurement of the ankle–brachial pressure index (ABPI), which is the ratio between the highest systolic ankle and brachial blood pressures. In health, the ABPI is over 1.0, in IC typically 0.5–0.9 and in CLI usually less than 0.5. Further investigation with duplex ultrasonography, MRI or CT with intravenous injection of contrast agents may be used to characterise the sites of involvement further. Intra-arterial digital subtraction angiography (IA-DSA) is usually reserved for those undergoing endovascular revascularisation. Other investigations should include a full blood count to look for evidence of treatable secondary causes, such as thrombocythaemia; measurement of lipids to check for evidence of hyperlipidaemia; and measurement of blood glucose to check for evidence of diabetes.

Management
Key elements of medical management are summarised in Box 16.60. This consists of smoking cessation (if applicable), taking regular exercise, antiplatelet therapy with low-dose aspirin or clopidogrel, therapy with a statin, and treatment of coexisting disease such as diabetes, hypertension or polycythaemia. Recently, the antiplatelet drug vorapaxar, a selective antagonist of the protease-activated receptor 1 (PAR-1) that regulates platelet activation, has been licensed in combination with either aspirin or clopidogrel in patients with PAD. The peripheral vasodilator cilostazol has been shown to improve walking distance and should be considered in patients who do not respond adequately to best medical therapy. Intervention with angioplasty, stenting, endarterectomy or bypass is usually considered only after medical therapy has been given at least 6 months to effect symptomatic improvement, and then just in patients who are severely disabled or whose livelihood is threatened by their disability. Subclavian artery disease is usually treated by means of angioplasty and stenting, as carotid–subclavian bypass surgery can be technically difficult.

Buerger’s disease
Buerger’s disease or thromboangiitis obliterans is an inflammatory disease of the arteries that is distinct from atherosclerosis and usually presents in young (20–30 years) male smokers. It is most common in those from the Mediterranean and North Africa. It characteristically affects distal arteries, giving rise to claudication in the feet or rest pain in the fingers or toes. Wrist and ankle pulses are absent but brachial and popliteal pulses are present. It may also affect the veins, giving rise to superficial thrombophlebitis. It often remits if the patient stops smoking. Symptomatic therapy with vasodilators such as prostacyclin and calcium antagonists or sympathectomy may also be helpful. Major limb amputation is the most frequent outcome if patients continue to smoke.

Raynaud’s syndrome
This common disorder affects 5–10% of young women aged 15–30 years in temperate climates. It does not progress to ulceration or infarction, and significant pain is unusual. The underlying cause is unclear and no investigation is necessary. The patient should be reassured and advised to avoid exposure to cold. Usually, no other treatment is required, although
Diseases of the aorta

Aortic aneurysm

Aortic aneurysm is defined to exist when there is an abnormal dilatation of the aortic lumen. The most common site is the infrarenal abdominal aorta. The suprarenal abdominal aorta and a variable length of the descending thoracic aorta may be affected in 10–20% of patients but the ascending aorta is usually spared. Abdominal aortic aneurysms (AAAs) affect men three times more commonly than women and are estimated to occur in about 5% of men over the age of 60 years.

Pathogenesis

The most common cause of aortic aneurysm is atherosclerosis, the risk factors for which have previously been described (p. 484). Genetic factors that predispose to hypertension, hyperlipidaemia and diabetes all play a role in the pathogenesis of aortic aneurysm but there appears to be an additional and specific genetic component since aortic aneurysm tends to run in families. This may explain in part why only some patients with risk factors for atheroma develop aneurysmal disease. Marfan’s syndrome is an inherited disorder of connective tissue that is associated with aortic aneurysm and aortic dissection (p. 508). The features and management of this disorder are discussed on page 508.

Clinical features

The clinical presentation is dependent on the site of the aneurysm. Thoracic aneurysms may typically present with acute severe chest pain (p. 176) but other features, including aortic regurgitation, compressive symptoms such as stridor (trachea, bronchus), hoarseness (recurrent laryngeal nerve) and superior vena cava syndrome, may occur (Fig. 16.72A). If the aneurysm erodes into an adjacent structure, such as the oesophagus or bronchus, the presentation may be with massive bleeding. AAAs affect the infrarenal segment of the aorta. They can present in a number of ways, as summarised in Box 16.62. The usual age at presentation is 65–75 years for elective presentations and 75–85 years for emergency presentations.

Investigations

Ultrasound is the best way of establishing the diagnosis of an abdominal aneurysm and of following up patients with asymptomatic aneurysms that are not yet large enough to warrant surgical repair. In the UK, a national screening programme for men over 65 years of age has been introduced using ultrasound scanning. For every 10,000 men scanned, 65 ruptures are prevented and 52 lives saved. CT provides more accurate information about the size and extent of the aneurysm, the surrounding structures and the presence of any other intra-abdominal pathology. It is the standard pre-operative investigation but is not suitable for surveillance because of the high cost and radiation dose.

Management

The risks of surgery generally outweigh the risks of rupture until an asymptomatic AAA has reached a maximum of 5.5 cm in diameter. All asymptomatic AAAs should be considered for repair, not only to rid the patient of symptoms but also because pain often predates rupture. Distal embolisation is a strong indication for repair, regardless of size, because otherwise limb loss is common. Most patients with a ruptured AAA do not survive to reach hospital, but if they do and surgery is thought to be appropriate, there must be no delay in getting them to the operating theatre to clamp the aorta.

Open AAA repair has been the treatment of choice in both the elective and the emergency settings, and entails replacing the aneurysmal segment with a prosthetic (usually Dacron) graft. The 30-day mortality for this procedure is approximately 5–8% for elective asymptomatic AAA, 10–20% for emergency asymptomatic AAA and 50% for ruptured AAA. However, patients who survive the operation to leave hospital have a long-term survival approaching that of the normal population. Increasingly, endovascular aneurysm repair (EVAR), using a stent graft introduced via the femoral arteries in the groin, is...
replacing open surgery. It is cost-effective and likely to become the treatment of choice for infrarenal AAA. It is possible to treat many suprarenal and thoraco-abdominal aneurysms by EVAR too. If the aneurysm is secondary to Marfan’s syndrome, treatment with β-blockers reduces the rate of aortic dilatation and the risk of rupture. Elective replacement of the ascending aorta may also be considered in patients with evidence of progressive aortic dilatation but carries a mortality of 5–10%.

**Aortic dissection**

Aortic dissection occurs when a breach in the integrity of the aortic wall allows arterial blood to enter the media, which is then split into two layers, creating a false lumen alongside the existing or true lumen (Fig. 16.72B). The aortic valve may be damaged and the branches of the aorta may be compromised. Typically, the false lumen eventually re-enters the true lumen, creating a double-barrelled aorta, but it may also rupture into the left pleural space or pericardium with fatal consequences. The peak incidence is in the sixth and seventh decades but dissection can occur in younger patients, usually in association with Marfan’s syndrome, pregnancy or trauma; men are affected twice as frequently as women.

**Pathogenesis**

The primary event is often a spontaneous or iatrogenic tear in the intima of the aorta; multiple tears or entry points are common. Other dissections are triggered by primary haemorrhage in the media of the aorta, which then ruptures through the intima into the true lumen. This form of spontaneous bleeding from the vasa vasorum is sometimes confined to the aortic wall, when it may present as a painful intramural haematoma. Aortic disease and hypertension are the most important aetiological factors but other conditions may also be implicated (Box 16.63). Chronic dissections may lead to aneurysmal dilatation of the aorta, and thoracic aneurysms may be complicated by dissection. It can therefore be difficult to identify the primary pathology.
Aortic dissection is classified anatomically and for management purposes into type A and type B (see Fig. 16.72B), involving or sparing the ascending aorta, respectively. Type A dissections account for two-thirds of cases and frequently also extend into the descending aorta.

**Clinical features**

Involvement of the ascending aorta typically gives rise to anterior chest pain, and involvement of the descending aorta to intrascapular back pain. The pain is typically described as ‘tearing’ and very abrupt in onset; collapse is common. Unless there is major haemorrhage, the patient is invariably hypertensive. There may be asymmetry of the brachial, carotid or femoral pulses and signs of aortic regurgitation. Occlusion of aortic branches may cause MI (coronary), stroke (carotid), paraplegia (spinal), mesenteric infarction with an acute abdomen (coeliac and superior mesenteric), renal failure (renal) and acute limb (usually leg) ischaemia.

**Investigations**

The investigations of choice are CT or MR angiography (Figs 16.73 and 16.74), both of which are highly specific and sensitive. A chest X-ray should be performed. It characteristically shows broadening of the upper mediastinum and distortion of the aortic ‘knuckle’ but these findings are absent in 10% of cases. A left-sided pleural effusion is common. The ECG may show left ventricular hypertrophy in patients with hypertension or, rarely, changes in the ST segment.

### Risk factors for aortic dissection

- Hypertension (in 80%)
- Atherosclerosis
- Coarctation
- Genetic:
  - Marfan’s syndrome
  - Ehlers–Danlos syndrome
- Fibromuscular dysplasia
- Previous cardiac surgery:
  - CABG
  - Aortic valve replacement
- Pregnancy (usually third trimester)
- Trauma
- Iatrogenic:
  - Cardiac catheterisation
  - Intra-aortic balloon pumping

(CABG = coronary artery bypass grafting)
of acute MI (usually inferior). Doppler echocardiography may show aortic regurgitation, a dilated aortic root and, occasionally, the flap of the dissection. TOE is particularly helpful because transthoracic echocardiography can provide images of the first 3–4 cm of the ascending aorta only (Fig. 16.75).

Management

The early mortality of acute dissection is approximately 1–5% per hour and so treatment is urgently required. Initial management comprises pain control and antihypertensive treatment. Type A dissections require emergency surgery to replace the ascending aorta. Type B aneurysms are treated medically unless there is actual or impending external rupture, or vital organ (gut, kidneys) or limb ischaemia, as the morbidity and mortality associated with surgery are very high. The aim of medical management is to maintain a mean arterial pressure (MAP) of 60–75 mmHg to reduce the force of the ejection of blood from the LV. First-line therapy is with β-blockers; the additional α-blocking properties of labetalol make it especially useful. Rate-limiting calcium channel blockers, such as verapamil or diltiazem, are used if β-blockers are contraindicated. Sodium nitroprusside may be considered if these fail to control BP adequately.

Percutaneous or minimal access endoluminal repair is sometimes possible and involves either ‘fenestrating’ (perforating) the intimal flap so that blood can return from the false to the true lumen (so decompressing the former), or implanting a stent graft placed from the femoral artery (see Fig. 16.74).

Aortitis

Syphilis is a rare cause of aortitis that characteristically produces saccular aneurysms of the ascending aorta containing calcification. Other rare conditions associated with aortitis include Takayasu’s disease (p. 1041), reactive arthritis (p. 1031), giant cell arteritis (p. 1042) and ankylosing spondylitis (p. 1028).

Marfan’s syndrome

Marfan’s syndrome is an inherited disorder of connective tissue that is associated with a high risk of aortic aneurysm and dissection. It is inherited in an autosomal dominant manner but some cases are due to new mutations. It is a rare disorder that is estimated to affect about 0.02% of the population. Marfan’s syndrome is caused by protein-coding mutations affecting the FBN1 gene, which encodes fibrillin, an extracellular matrix protein. The causal mutations disrupt the mechanical integrity of connective tissue, giving rise to a wide range of clinical features.

Clinical features

Aortic dissection and aneurysm are the most serious complications of Marfan’s syndrome but many other clinical manifestations may be observed. These include aortic and mitral valve regurgitation; skin laxity and joint hypermobility; abnormalities of body habitus, including long arms, legs and fingers (arachnodactyly), scoliosis, pectus excavatum and a high-arched palate; ocular abnormalities, such as lens dislocation and retinal detachment; and an increased risk of pneumothorax.

Investigations

The diagnosis is usually suspected on the basis of the characteristic clinical features and can be confirmed by genetic testing. Imaging by chest X-ray may reveal evidence of aortic dilatation but echocardiography is more sensitive and can also demonstrate valvular disease, if present. Patients with Marfan’s syndrome should undergo serial monitoring of the aortic root by echocardiography; if evidence of dilatation is observed, then elective surgery should be considered.

Coarctation of the aorta

Coarctation of the aorta is the term used to describe a narrowing distal to the origin of the left subclavian artery. It is most commonly due to congenital heart disease (p. 531), but narrowing of the aorta leading to similar symptoms can occur in other conditions such as Takayasu’s arteritis (p. 1041) and trauma. Diagnosis and management of coarctation are discussed on page 534.

Hypertension

The risk of cardiovascular diseases such as stroke and CAD is closely related to levels of BP. BP follows a normal distribution in the general population and there is no specific cut-off above which the risk of cardiovascular risk suddenly increases. The diagnosis of hypertension is therefore made when systolic and diastolic values rise above a specific threshold that corresponds to the level of BP at which the risk of cardiovascular complications and benefits of treatment outweigh the treatment costs and potential side-effects of therapy. The British Hypertension Society classification, provided in Box 16.64, defines mild hypertension as existing when the BP is above 140/90 mmHg. Similar thresholds have been published by the European Society of Hypertension and the WHO–International Society of Hypertension. The cardiovascular risks associated with high BP depend on the combination of risk factors in an individual, such as age, gender, weight, physical activity, smoking, family history, serum cholesterol, diabetes mellitus and pre-existing vascular disease.
Diseases of the aorta

• 509

16

and cerebrovascular disease, particularly if other risk factors are present. These structural changes in the vasculature often perpetuate and aggravate hypertension by increasing peripheral vascular resistance and reducing renal blood flow, thereby activating the renin–angiotensin–aldosterone axis (p. 461).

Clinical features

Hypertension is usually asymptomatic until the diagnosis is made at a routine physical examination or when a complication arises. Reflecting this fact, a BP check is advisable every 5 years in adults over 40 years of age to pick up occult hypertension. Sometimes clinical features may be observed that can give a clue to the underlying cause of hypertension. These include radio-femoral delay in patients with coarctation of the aorta (see Fig. 16.93, p. 534), enlarged kidneys in patients with polycystic kidney disease (p. 405), abdominal bruits that may suggest renal artery stenosis (p. 406), and the characteristic facies and habitus of Cushing’s syndrome (Box 16.65). Examination may also reveal evidence of risk factors for hypertension, such as central obesity and hyperlipidaemia. Other signs may be observed that are due to the complications of hypertension. These include signs of left ventricular hypertrophy, accentuation of the aortic component of the second heart sound, and a fourth heart sound. AF is common and may be due to diastolic dysfunction caused by left ventricular hypertrophy or the effects of CAD.

Severe hypertension can cause left ventricular failure in the absence of CAD, particularly when there is an impairment of renal function. The optic fundi are often abnormal (see Fig. 16.76 below) and there may be evidence of generalised atheroma or

Pathogenesis

Many factors may contribute to the regulation of BP and the development of hypertension, including renal dysfunction, peripheral resistance, vessel tone, endothelial dysfunction, autonomic tone, insulin resistance and neurohumoral factors. In more than 95% of cases, however, no specific underlying cause of hypertension can be found. Such patients are said to have essential hypertension. Hypertension is more common in some ethnic groups, particularly African Americans and Japanese, and approximately 40–60% is explained by genetic factors. Age is a strong risk factor in all ethnic groups. Important environmental factors include a high salt intake, heavy consumption of alcohol, obesity and lack of exercise. Impaired intrauterine growth and low birth weight are associated with an increased risk of hypertension later in life. In about 5% of cases, hypertension is secondary to a specific disease, as summarised in Box 16.65.

Hypertension has a number of adverse effects on the cardiovascular system. In larger arteries (>1 mm in diameter), the internal elastic lamina is thickened, smooth muscle is hypertrophied and fibrous tissue is deposited. The vessels dilate and become tortuous, and their walls become less compliant. In smaller arteries (<1 mm), hyaline arteriosclerosis occurs in the wall, the lumen narrows and aneurysms may develop. Widespread atheroma develops and may lead to coronary

specific complications, such as aortic aneurysm, PAD or stroke. Examination of the optic fundi reveals a gradation of changes linked to the severity of hypertension; fundoscopy can, therefore, provide an indication of the arteriolar damage occurring elsewhere (Box 16.66). ‘Cotton wool’ exudates are associated with retinal ischaemia or infarction, and fade in a few weeks (Fig. 16.76A). ‘Hard’ exudates (small, white, dense deposits of lipid) and microaneurysms (‘dot’ haemorrhages) are more characteristic of diabetic retinopathy (see Fig. 27.8, p. 1176). Hypertension is also associated with central retinal vein thrombosis (Fig. 16.76B).

**Investigations**

A decision to embark on antihypertensive therapy effectively commits the patient to life-long treatment, so readings must be as accurate as possible. The objectives are to:

- confirm the diagnosis by obtaining accurate, representative BP measurements
- identify contributory factors and any underlying causes
- assess other risk factors and quantify cardiovascular risk
- detect any complications that are already present
- identify comorbidity that may influence the choice of antihypertensive therapy.

**Blood pressure measurements**

BP measurements should be made to the nearest 2 mmHg, in the sitting position with the arm supported, and repeated after 5 minutes’ rest if the first recording is high (Box 16.67). To avoid spuriously high readings in obese subjects, the cuff should contain a bladder that encompasses at least two-thirds of the arm circumference. Exercise, anxiety, discomfort and unfamiliar surroundings can all lead to a transient rise in BP. Sphygmomanometry, particularly when performed by a doctor, can cause a transient elevation in BP, which has been termed ‘white coat’ hypertension. It has been estimated that up to 20% of patients who are found to have raised BP at outpatient clinics have a normal BP when it is recorded by automated devices used at home. The risk of cardiovascular disease in these patients is less than that in patients with sustained hypertension but greater than that in normotensive subjects. If clinic BP measurements show borderline levels of BP or if white coat hypertension is suspected, then ambulatory measurement or home-based measurements may be of value in confirming the diagnosis.

**Ambulatory blood pressure measurements**

A series of automated ambulatory BP measurements obtained over 24 hours or longer provide a better profile than a limited number of clinic readings and correlate more closely with evidence of target organ damage than casual BP measurements. Treatment thresholds and targets (see Box 16.71 below) must be adjusted downwards, however, because ambulatory BP readings are systematically lower (approximately 12/7 mmHg) than clinic measurements. The average ambulatory daytime (not 24-hour or night-time) BP should be used to guide management decisions.

**Home blood pressure measurements**

Patients can measure their own BP at home using a range of commercially available semi-automatic devices. The value of such measurements is less well established and is dependent on the environment and timing of the readings measured. Home or ambulatory BP measurements are particularly helpful in patients with unusually labile BP, those with refractory hypertension, those who may have symptomatic hypotension, and those in whom white coat hypertension is suspected.

**Other investigations**

All hypertensive patients should undergo a limited number of investigations (Box 16.68) but additional investigations are appropriate in patients younger than 40 years of age or those with resistant hypertension (Box 16.69). Family history, lifestyle (exercise, salt intake, smoking habit) and other risk factors should also be recorded. A careful history will identify those patients with drug- or alcohol-induced hypertension and may elicit the symptoms of other causes of secondary hypertension, such as phaeochromocytoma (paroxysmal headache, palpitation and sweating, p. 675) or complications such as CAD.

**Management**

The objective of antihypertensive therapy is to reduce the incidence of adverse cardiovascular events, particularly CAD, stroke and heart failure. Randomised controlled trials have
demonstrated that antihypertensive therapy can reduce the incidence of stroke and, to a lesser extent, CAD. The relative benefits (approximately 30% reduction in risk of stroke and 20% reduction in risk of CAD) are similar in all patient groups, so the absolute benefit of treatment (total number of events prevented) is greatest in those at highest risk. For example, to extrapolate from the Medical Research Council (MRC) Mild Hypertension Trial (1985), 566 young patients would have to be treated with bendroflumethiazide for 1 year to prevent 1 stroke, while in the MRC trial of antihypertensive treatment in the elderly (1992), 1 stroke was prevented for every 286 patients treated for 1 year.

A formal estimate of absolute cardiovascular risk, which takes account of all the relevant risk factors, may help to determine whether the likely benefits of therapy will outweigh its costs and hazards. A variety of risk algorithms are available for this purpose, such as the Joint British Societies risk calculator (Fig. 16.77 and see “Further information”). Most of the excess morbidity and mortality associated with hypertension are attributable to CAD and many treatment guidelines are therefore based on estimates of the 10-year CAD risk. Total cardiovascular risk can be estimated by multiplying CAD risk by 4/3 (i.e. if CAD risk is 30%, cardiovascular risk is 40%). The value of this approach can be illustrated by comparing the two hypothetical cases on page 487.

**Intervention thresholds**

Systolic BP and diastolic BP are both powerful predictors of cardiovascular risk. The British Hypertension Society management

---

**Specialised investigation of hypertension**

- Chest X-ray: to detect cardiomegaly, heart failure, coarctation of the aorta
- Ambulatory BP recording: to assess borderline or ‘white coat’ hypertension
- Echocardiogram: to detect or quantify left ventricular hypertrophy
- Renal ultrasound: to detect possible renal disease
- Renal angiography: to detect or confirm the presence of renal artery stenosis
- Urinary catecholamines: to detect possible phaeochromocytoma (p. 675)
- Urinary cortisol and dexamethasone suppression test: to detect possible Cushing’s syndrome (p. 666)
- Plasma renin activity and aldosterone: to detect possible primary aldosteronism (p. 674)

---

**Fig. 16.77 Example of cardiovascular risk prediction chart for non-diabetic men.** Cardiovascular risk is predicted from the patient’s age, sex, smoking habit, BP and cholesterol ratio. The ratio of total to high-density lipoprotein (HDL) cholesterol can be determined in a non-fasting blood sample. Where HDL cholesterol concentration is unknown, it should be assumed to be 1 mmol/L; the lipid scale should be used as total serum cholesterol. Current guidelines suggest initiation of primary prevention in individuals with a 10-year cardiovascular risk ≥20%. Patients with diabetes mellitus should be assumed to have a 10-year cardiovascular risk of ≥20% and receive secondary prevention therapy. Modified charts exist for women. For further details, see [www.who.int/cardiovascular_diseases/guidelines/Pocket_GL_information](http://www.who.int/cardiovascular_diseases/guidelines/Pocket_GL_information).

- To estimate an individual’s absolute 10-year risk of developing cardiovascular disease (CVD), choose the panel for the appropriate gender, smoking status and age. Within this, define the level of risk from the point where the coordinates for systolic blood pressure (SBP) and ratio of the total to HDL-cholesterol cross.
- Highest-risk individuals (red areas) are those whose 10-year CVD risk exceeds 20%, which is approximately equivalent to a 10-year coronary artery disease risk of >15%. As a minimum, those with CVD risk >30% (shown by the line within the red area) should be targeted and treated now. When resources allow, others with a CVD risk >20% should be targeted progressively.
- The chart also assists in identification of individuals with a moderately high 10-year CVD risk, in the range of 10–20% (orange area) and those in whom it is <10% (green area).
- Smoking status should reflect lifetime exposure to tobacco. For further information, see [www.bhf.org.uk](http://www.bhf.org.uk). From *Joint British Societies Cardiovascular Risk Prediction Chart*, reproduced with permission from the University of Manchester.
guidelines therefore utilise both readings, and treatment should be initiated if they exceed the given threshold (Fig. 16.78).

Patients with diabetes or cardiovascular disease are at particularly high risk and the threshold for initiating antihypertensive therapy is therefore lower (≥140/90 mmHg) in these patient groups. The thresholds for treatment in the elderly are the same as for younger patients (Box 16.70).

**Treatment targets**

The optimum BP for reduction of major cardiovascular events has been found to be 139/83 mmHg, and even lower in patients with diabetes mellitus. Moreover, reducing BP below this level causes no harm. The targets suggested by the British Hypertension Society (Box 16.71) are ambitious. Primary care strategies have been devised to improve screening and detection of hypertension that, in the past, remained undetected in up to half of patients.

---

**Fig. 16.78** Management of hypertension: British Hypertension Society guidelines. *Signs of papilloedema or retinal haemorrhage. 1Labile or postural hypotension, headache, palpitations, pallor and diaphoresis. (ABPM = ambulatory blood pressure monitoring; HBPM = home blood pressure monitoring)*

From NICE Clinical Guideline 127 – Hypertension in adults; August 2011.

---

**Box 16.70 Hypertension in old age**

- **Prevalence:** Hypertension affects more than half of all people over the age of 60 years (including isolated systolic hypertension).
- **Risks:** Hypertension is the most important risk factor for myocardial infarction, heart failure and stroke in older people.
- **Benefit of treatment:** Absolute benefit from therapy is greatest in older people (at least up to age 80 years).
- **Target blood pressure:** Targets be relaxed in older people to 150/90 mmHg.
- **Tolerance of treatment:** Antihypertensives are tolerated as well as in younger patients.
- **Drug of choice:** Low-dose thiazides but, in the presence of coexistent disease such as gout or diabetes, other agents may be more appropriate.
of affected individuals. Application of new guidelines should help establish patients on appropriate treatment, and allow step-up if lifestyle modification and first-line drug therapy fail to control hypertension.

Patients taking antihypertensive therapy require follow-up at regular intervals to monitor BP, minimise side-effects and reinforce lifestyle advice.

Non-drug therapy

Appropriate lifestyle measures may obviate the need for drug therapy in patients with borderline hypertension, reduce the dose and/or the number of drugs required in patients with established hypertension, and directly reduce cardiovascular risk.

Correcting obesity, reducing alcohol intake, restricting salt intake, taking regular physical exercise and increasing consumption of fruit and vegetables can all lower BP. Moreover, stopping smoking, eating oily fish and adopting a diet that is low in saturated fat may produce further reductions in cardiovascular risk that are independent of changes in BP.

Drug therapy

Thiazides The mechanism of action of these drugs is incompletely understood and it may take up to a month for the maximum effect to be observed. An appropriate daily dose is 2.5 mg bendroflumethiazide or 0.5 mg cyclopenthiazide. More potent loop diuretics, such as furosemide (40 mg daily) or bumetanide (1 mg daily), have few advantages over thiazides in the treatment of hypertension, unless there is substantial renal impairment or they are used in conjunction with an ACE inhibitor.

ACE inhibitors ACE inhibitors (enalapril 20 mg daily, ramipril 5–10 mg daily or lisinopril 10–40 mg daily) are effective and usually well tolerated. They should be used with care in patients with impaired renal function or renal artery stenosis because they can reduce glomerular filtration rate and precipitate renal failure. Electrolytes and creatinine should be checked before and 1–2 weeks after commencing therapy. Side-effects include first-dose hypotension, cough, rash, hyperkalaemia and renal dysfunction.

Angiotensin receptor blockers ARBs (irbesartan 150–300 mg daily, valsartan 40–160 mg daily) have similar efficacy to ACE inhibitors but they do not cause cough and are better tolerated.

Calcium channel antagonists Amlodipine (5–10 mg daily) and nifedipine (30–90 mg daily) are effective and usually well-tolerated antihypertensive drugs that are particularly useful in older people. Side-effects include flushing, palpitations and fluid retention. The rate-limiting calcium channel antagonists (diltiazem 200–300 mg daily, verapamil 240 mg daily) can be useful when hypertension coexists with angina but may cause bradycardia. The main side-effect of verapamil is constipation.

Beta-blockers These are no longer used as first-line antihypertensive therapy, except in patients with another indication for the drug such as angina. Metoprolol (100–200 mg daily), atenolol (50–100 mg daily) and bisoprolol (5–10 mg daily), which preferentially block cardiac β1-adrenoceptors, should be used rather than non-selective agents that also block β2-adrenoceptors, which mediate vasodilatation and bronchodilatation.

Combined β- and α-blockers Labetalol (200 mg–2.4 g daily in divided doses) and carvedilol (6.25–25 mg twice daily) are combined β- and α-adrenoceptor antagonists that are sometimes more effective than pure β-blockers. Labetalol can be used as an infusion in malignant phase hypertension (see below).

Other vasodilators A variety of other vasodilators may be used. These include the α1-adrenoceptor antagonists prazosin (0.5–20 mg daily in divided doses), indoramin (50–300 mg twice daily) and doxazosin (1–16 mg daily), and drugs that act directly on vascular smooth muscle, such as hydralazine (25–100 mg twice daily) and minoxidil (10–50 mg daily). Side-effects include first-dose and postural hypotension, headache, tachycardia and fluid retention. Minoxidil also causes increased facial hair and is therefore unsuitable for female patients.

Aspirin Antiplatelet therapy is a powerful means of reducing cardiovascular risk but may cause bleeding, particularly intracerebral haemorrhage, in a small number of patients. The benefits are thought to outweigh the risks in hypertensive patients aged 50 years or over who have well-controlled BP and either target organ damage or diabetes or a 10-year CAD risk of at least 15% (or 10-year cardiovascular disease risk of at least 20%).

Statins Treating hyperlipidaemia can produce a substantial reduction in cardiovascular risk. These drugs are strongly indicated in patients who have established vascular disease, or hypertension with a high (at least 10% in 10 years) risk of developing cardiovascular disease (p. 376).

Choice of antihypertensive drug

Trials that have compared thiazides, calcium antagonists, ACE inhibitors and ARBs have not shown consistent differences in outcome, efficacy, side-effects or quality of life. Beta-blockers, which previously featured as first-line therapy in guidelines, have a weaker evidence base. The choice of antihypertensive therapy is initially dictated by the patient’s age and ethnic background, although cost and convenience will influence the exact drug and preparation used. Response to initial therapy and side-effects guide subsequent treatment. Comorbid conditions also have an influence on initial drug selection (Box 16.72); for example, a β-blocker might be the most appropriate treatment for a patient with angina. Thiazide diuretics and dihydropyridine calcium channel antagonists are the most suitable drugs for treatment in older people.

Combination therapy

Although some patients can be treated with a single antihypertensive drug, a combination of drugs is often required to achieve optimal control (Fig. 16.79). Combination therapy may be desirable for other reasons; for example, low-dose therapy with two drugs may produce fewer unwanted effects than treatment with the maximum dose of a single drug. Some drug combinations have complementary or synergistic actions; for example, thiazides increase activity of the renin–angiotensin system, while ACE inhibitors block it.
compromise tissue perfusion due to altered autoregulation and
In accelerated phase hypertension, lowering BP too quickly may
Management may occur and, if this is untreated, death occurs within months. Left ventricular failure (grade 3 or 4), renal dysfunction (especially proteinuria) and/or rapidly progressive end-organ damage, such as retinopathy (fibrinoid necrosis) and by intravascular thrombosis. The diagnosis is based on evidence of high BP and rapidly progressive end-organ damage, such as retinopathy (grade 3 or 4), renal dysfunction (especially proteinuria) and/or hypertensive encephalopathy (see above). Left ventricular failure may occur and, if this is untreated, death occurs within months.

Accelerated hypertension

Accelerated or malignant hypertension is a rare condition that can complicate hypertension of any aetiology. It is characterised by accelerated microvascular damage with necrosis in the walls of small arteries and arterioles (fibrinoid necrosis) and by intravascular thrombosis. The diagnosis is based on evidence of high BP and rapidly progressive end-organ damage, such as retinopathy (grade 3 or 4), renal dysfunction (especially proteinuria) and/or hypertensive encephalopathy (see above). Left ventricular failure may occur and, if this is untreated, death occurs within months.

Management

In accelerated phase hypertension, lowering BP too quickly may compromise tissue perfusion due to altered autoregulation and can cause cerebral damage, including occipital blindness, and precipitate coronary or renal insufficiency. Even in the presence of cardiac failure or hypertensive encephalopathy, a controlled reduction to a level of about 150/90 mmHg over a period of 24–48 hours is ideal.

In most patients, it is possible to avoid parenteral therapy and bring BP under control with bed rest and oral drug therapy. Intravenous or intramuscular labetalol (2 mg/min to a maximum of 200 mg), intravenous GTN (0.6–1.2 mg/hr), intramuscular hydralazine (5 or 10 mg aliquots repeated at half-hourly intervals) and intravenous sodium nitroprusside (0.3–1.0 μg/kg body weight/min) are all effective but require careful supervision, preferably in a high-dependency unit.

Diseases of the heart valves

The heart valves allow forward movement of blood through the cardiac chambers when they are open and prevent backward flow when they are closed. Diseased valve may become narrowed, obstructing forward flow, or become leaky, causing backward flow or regurgitation. Breathlessness is a common symptom of valve disease, and acute severe breathlessness may be a presenting symptom of valve failure. The causes of this are shown in Box 16.73. Predisposition to valvular disease may be genetically determined, can arise as the result of rheumatic fever or infections, or can occur in association with dilatation of
Incidence is about 0.5 cases per 100,000, but remains endemic in the Indian subcontinent, Africa and South America. Recent studies indicate that the current incidence of rheumatic heart disease in India ranges between 13 and 150 cases per 100,000 population per year and it is by far the most common cause of acquired heart disease in childhood and adolescence in that country.

Pathogenesis

The condition is triggered by an immune-mediated delayed response to infection with specific strains of group A streptococci, which have antigens that cross-react with cardiac myosin and sarcolemmal membrane proteins. Antibodies produced against the streptococcal antigens cause inflammation in the endocardium, myocardium and pericardium, as well as the joints and skin. Histologically, fibrinoid degeneration is seen in the collagen of connective tissues. Aschoff nodules are pathognomonic and occur only in the heart. They are composed of multinucleated giant cells surrounded by macrophages and T lymphocytes, and are not seen until the subacute or chronic phases of rheumatic carditis.

Clinical features

Acute rheumatic fever is a multisystem disorder that usually presents with fever, anorexia, lethargy and joint pain, 2–3 weeks after an episode of streptococcal pharyngitis. There may be no history of sore throat, however. Arthritis occurs in approximately 75% of patients. Other features include rash, subcutaneous nodules, carditis and neurological changes (Fig. 16.80). The diagnosis, made using the revised Jones criteria (Box 16.75), is based on two or more major manifestations, or one major and two or more minor manifestations, along with evidence of preceding streptococcal infection. A presumptive diagnosis of acute rheumatic fever can be made without evidence of preceding streptococcal infection in cases of isolated chorea or pancarditis, if other causes of these have been excluded. In cases of established rheumatic heart disease or prior rheumatic fever, a diagnosis of acute rheumatic fever can be made based only on the presence of multiple minor criteria and evidence of preceding group A streptococcal pharyngitis.

Carditis

Rheumatic fever causes a pancarditis involving the endocardium, myocardium and pericardium to varying degrees. Its incidence declines with increasing age, ranging from 90% at 3 years to around 30% in adolescence. It may manifest as breathlessness (due to heart failure or pericardial effusion), palpitations or chest pain (usually due to pericarditis or pancarditis). Other features include tachycardia, cardiac enlargement and new or changed
murmurs. A soft systolic murmur due to mitral regurgitation is very common. A soft mid-diastolic murmur (the Carey Coombs murmur) is typically due to valvulitis, with nodules forming on the mitral valve leaflets. Aortic regurgitation occurs in 50% of cases but the tricuspid and pulmonary valves are rarely involved. Pericarditis may cause chest pain, a pericardial friction rub and precordial tenderness. Cardiac failure may be due to myocardial dysfunction or valvular regurgitation. ECG evidence commonly includes ST and T wave changes. Conduction defects, including AV block, sometimes occur and may cause syncope.

**Arthritis**

This is the most common major manifestation and occurs early when streptococcal antibody titres are high. An acute painful, asymmetric and migratory inflammation of the large joints typically affects the knees, ankles, elbows and wrists. The joints are involved in quick succession and are usually red, swollen and tender for between a day and 4 weeks.

**Skin lesions**

Erythema marginatum occurs in less than 5% of patients. The lesions start as red macules that fade in the centre but remain red at the edges, and occur mainly on the trunk and proximal extremities but not the face. The resulting red rings or ‘margins’ may coalesce or overlap (Fig. 16.80). Subcutaneous nodules occur in 5–7% of patients. They are small (0.5–2.0 cm), firm and painless, and are best felt over extensor surfaces of bone or tendons. They typically appear more than 3 weeks after the onset of other manifestations and therefore help to confirm rather than make the diagnosis.

**Sydenham’s chorea**

Sydenham’s chorea, also known as St Vitus dance, is a late neurological manifestation that appears at least 3 months after the episode of acute rheumatic fever, when all the other signs may have disappeared. It occurs in up to one-third of cases and is more common in females. Emotional lability may be the first feature and is typically followed by purposeless, involuntary, choreiform movements of the hands, feet or face. Speech may be explosive and halting. Spontaneous recovery usually occurs within a few months. Approximately one-quarter of affected patients will go on to develop chronic rheumatic valve disease.

**Other features**

Other systemic manifestations, such as pleurisy, pleural effusion and pneumonia, may occur but are rare.

**Investigations**

Blood should be taken for measurement of ESR and CRP since these are useful for monitoring progress of the disease (Box 16.76). Throat cultures should be taken but positive results are obtained in only 10–25% of cases since the infection has often resolved by the time of presentation. Serology for antistreptolysin O antibodies (ASO) should be performed. Raised levels provide supportive evidence for the diagnosis but are normal in one-fifth of adult cases of rheumatic fever and most cases of chorea. Echocardiography should be carried out and typically shows mitral regurgitation with dilatation of the mitral annulus and prolapse of the anterior mitral leaflet; it may also demonstrate aortic regurgitation and pericardial effusion.

**Management**

The aims of management are to limit cardiac damage and relieve symptoms.

**Bed rest**

Bed rest is important, as it lessens joint pain and reduces cardiac workload. The duration should be guided by symptoms, along with temperature, leucocyte count and ESR, and should be continued until these have settled. Patients can then return to normal physical activity but strenuous exercise should be avoided in those who have had carditis.

**Treatment of cardiac failure**

Cardiac failure should be treated as necessary. Some patients, particularly those in early adolescence, can develop a fulminant form of the disease with severe mitral regurgitation and, sometimes, concomitant aortic regurgitation. If heart failure in these cases

**Erythema marginatum**

does not respond to medical treatment, valve replacement may be necessary and is often associated with a dramatic decline in rheumatic activity. Occasionally, AV block may occur but is seldom progressive and usually resolves spontaneously. Rarely, pacemaker insertion may be required.

**Antibiotics**

A single dose of benzathine benzylpenicillin (1.2 million U IM) or oral phenoxymethylpenicillin (250 mg 4 times daily for 10 days) should be given on diagnosis to eliminate any residual streptococcal infection. If the patient is penicillin-allergic, erythromycin or a cephalosporin may be used. Patients are susceptible to further attacks of rheumatic fever if another streptococcal infection occurs, and long-term prophylaxis with penicillin should be given with oral phenoxymethylpenicillin (250 mg twice daily) or as benzathine benzylpenicillin (1.2 million U IM monthly), if adherence is in doubt. Sulfadiazine or erythromycin may be used if the patient is allergic to penicillin; sulphonamides prevent infection but are not effective in the eradication of group A streptococci. Further attacks of rheumatic fever are unusual after the age of 21, when antibiotic treatment can usually be stopped. The duration of prophylaxis should be extended if an attack has occurred in the last 5 years, or if the patient lives in an area of high prevalence and has an occupation (such as teaching) with a high risk of exposure to streptococcal infection. In those with residual heart disease, prophylaxis should continue until 10 years after the last episode or 40 years of age, whichever is later. While long-term antibiotic prophylaxis prevents further attacks of acute rheumatic fever, it does not protect against infective endocarditis.

**Aspirin**

This usually relieves the symptoms of arthritis rapidly and a response within 24 hours helps confirm the diagnosis. A reasonable starting dose is 60 mg/kg body weight/day, divided into six doses. In adults, 100 mg/kg per day may be needed up to the limits of tolerance or a maximum of 8 g per day. Mild toxicity includes nausea, tinnitus and deafness; vomiting, tachypnoea and acidosis are more serious. Aspirin should be continued until the ESR has fallen and then gradually tailed off.

**Glucocorticoids**

These produce more rapid symptomatic relief than aspirin and are indicated in cases with carditis or severe arthritis. There is no evidence that long-term steroids are beneficial. Prednisolone (1.0–2.0 mg/kg per day in divided doses) should be continued until the ESR is normal and then tailed off.

**Chronic rheumatic heart disease**

Chronic valvular heart disease develops in at least half of those affected by rheumatic fever with carditis. Two-thirds of cases occur in women. Some episodes of rheumatic fever pass unrecognised and it is possible to elicit a history of rheumatic fever or chorea in only about half of all patients with chronic rheumatic heart disease.

The mitral valve is affected in more than 90% of cases; the aortic valve is the next most frequently involved, followed by the tricuspid and then the pulmonary valve. Isolated mitral stenosis accounts for about 25% of all cases, and an additional 40% have mixed mitral stenosis and regurgitation.

**Pathogenesis**

The main pathological process in chronic rheumatic heart disease is progressive fibrosis. The heart valves are predominantly affected but involvement of the pericardium and myocardium also occurs and may contribute to heart failure and conduction disorders. Fusion of the mitral valve commissures and shortening of the chordae tendineae may lead to mitral stenosis with or without regurgitation. Similar changes in the aortic and tricuspid valves produce distortion and rigidity of the cusps, leading to stenosis and regurgitation. Once a valve has been damaged, the altered haemodynamic stresses perpetuate and extend the damage, even in the absence of a continuing rheumatic process.

**Mitrail valve disease**

**Mitrail stenosis**

Mitrail stenosis is almost always rheumatic in origin, although in older people it can be caused by heavy calcification of the mitral valve. There is also a rare form of congenital mitral stenosis.

**Pathogenesis**

In rheumatic mitral stenosis, the mitral valve orifice is slowly diminished by progressive fibrosis, calcification of the valve leaflets, and fusion of the cusps and subvalvular apparatus. The mitral valve orifice is normally about 5 cm² in diastole but can be reduced to <1 cm² in severe mitral stenosis. The patient is usually asymptomatic until the orifice is <2 cm². As stenosis progresses, left ventricular filling becomes more dependent on left atrial contraction. There is dilatation and hypertrophy of the LA and left atrial pressure rises, leading to pulmonary venous congestion and breathlessness. Any increase in heart rate shortens diastole when the mitral valve is open and produces a further rise in left atrial pressure. Situations that demand an increase in cardiac output, such as pregnancy and exercise, also increase left atrial pressure and are poorly tolerated.

Atrial fibrillation is very common due to progressive dilatation of the LA. Its onset often precipitates pulmonary oedema because the accompanying tachycardia and loss of atrial contraction lead to marked haemodynamic deterioration and a rapid rise in left atrial pressure. In the absence of AF, a more gradual rise in left atrial pressure may occur. In the presence or absence of AF, pulmonary hypertension may occur, which can protect the patient from pulmonary oedema. Pulmonary hypertension leads to right ventricular hypertrophy and dilatation, tricuspid regurgitation and right heart failure. Fewer than 20% of patients...
remain in sinus rhythm but many of these have a small fibrotic LA and severe pulmonary hypertension.

**Clinical features**

Effort-related dyspnoea is usually the dominant symptom (Box 16.77). Typically, exercise tolerance diminishes very slowly over many years until symptoms eventually occur at rest. Patients frequently do not appreciate the extent of their disability until the diagnosis is made and their valve disease is treated. Acute pulmonary oedema or pulmonary hypertension can lead to haemoptysis. Fatigue is a common symptom due to a low cardiac output. Thromboembolism is a common complication, especially in patients with AF. Prior to the advent of anticoagulant therapy, emboli caused one-quarter of all deaths.

The physical signs of mitral stenosis are often found before symptoms develop and their recognition is of particular importance in pregnancy. The forces that open and close the mitral valve increase as left atrial pressure rises. The first heart sound (S1) is therefore loud and can be palpable (tapping apex beat). An opening snap may be audible and moves closer to the second sound (S2) as the stenosis becomes more severe and left atrial pressure rises. However, the first heart sound and opening snap may be inaudible if the valve is heavily calcified.

Turbulent flow produces the characteristic low-pitched mid-diastolic murmur and sometimes a thrill (Fig. 16.81). The murmur is accentuated by exercise and during atrial systole (pre-systolic accentuation). Early in the disease, a pre-systolic murmur may be

**Fig. 16.81** Mitral stenosis: murmur and the diastolic pressure gradient between left atrium (LA) and left ventricle (LV). (Mean gradient is reflected by the area between LA and LV in diastole.) The first heart sound is loud, and there is an opening snap (OS) and mid-diastolic murmur (MDM) with pre-systolic accentuation. **A** Echocardiogram showing reduced opening of the mitral valve in diastole. **B** Colour Doppler showing turbulent flow.
the only auscultatory abnormality, but in patients with symptoms, the murmur extends from the opening snap to the first heart sound. Coexisting mitral regurgitation causes a pansystolic murmur that radiates towards the axilla.

Pulmonary hypertension may ultimately lead to right ventricular hypertrophy and dilatation with secondary tricuspid regurgitation, which causes a systolic murmur and giant ‘v waves’ in the venous pulse.

**Investigations**

Doppler echocardiography is the investigation of choice for evaluation of suspected mitral stenosis (Fig. 16.81). Cardiac catheterisation may also be required if surgery or valvuloplasty is being considered, to screen for coexisting conditions such as CAD. The ECG may show either AF or bifid P waves (P mitrale) associated with left atrial hypertrophy (Box 16.78). A typical chest X-ray is shown in Figure 16.9 (p. 451).

**Management**

Patients with mild symptoms can be treated medically but intervention by balloon valvuloplasty, mitral valvotomy or mitral valve replacement should be considered if the patient remains symptomatic despite medical treatment or if pulmonary hypertension develops.

**Medical management**

This consists of anticoagulation to reduce the risk of systemic embolism, ventricular rate control with digoxin, β-blockers or rate-limiting calcium antagonists in AF, and diuretic to control pulmonary congestion. Antibiotic prophylaxis against infective endocarditis is no longer routinely recommended.

**Mitral balloon valvuloplasty and valve replacement**

Valvuloplasty is the treatment of choice if specific criteria are fulfilled (Box 16.79 and Fig. 16.82), although surgical closed or open mitral valvotomy is an acceptable alternative. Patients who have undergone mitral valvuloplasty or valvotomy should be followed up at 1–2-yearly intervals because restenosis may occur. Clinical symptoms and signs are a guide to the severity of mitral restenosis but Doppler echocardiography provides a more accurate assessment.

Valve replacement is indicated if there is substantial mitral reflux or if the valve is rigid and calcified (p. 526).

**Mitral regurgitation**

Rheumatic disease is the principal cause in countries where rheumatic fever is common but elsewhere, including in the UK, other causes are more important (Box 16.80). Mitral regurgitation may also follow mitral valvotomy or valvuloplasty.

**Pathogenesis**

Chronic mitral regurgitation causes gradual dilatation of the LA with little increase in pressure and therefore relatively few symptoms. Nevertheless, the LV dilates slowly and the left ventricular diastolic and left atrial pressures gradually increase as a result of chronic volume overload of the LV. In contrast, acute mitral regurgitation causes a rapid rise in left atrial pressure (because left atrial compliance is normal) and marked symptomatic deterioration.

*For comprehensive guidelines on valvular heart disease, see www.acc.org.*

**16.79 Criteria for mitral valvuloplasty**

- Significant symptoms
- Isolated mitral stenosis
- No (or trivial) mitral regurgitation
- Mobile, non-calcified valve/subvalve apparatus on echo
- Left atrium free of thrombus

**Fig. 16.82 Mitral valvuloplasty.** A guidewire is introduced into the right atrium (RA) from the femoral vein and the inferior vena cava (IVC). The inter-atrial septum is punctured, providing access to the left atrium and mitral valve. A balloon catheter is then advanced over the guidewire across the mitral valve and the balloon dilated to stretch the valve and reduce the degree of stenosis.

**16.80 Causes of mitral regurgitation**

- Mitral valve prolapse
- Dilatation of the left ventricle and mitral valve ring (e.g. coronary artery disease, cardiomyopathy)
- Damage to valve cusps and chordae (e.g. rheumatic heart disease, endocarditis)
- Ischaemia or infarction of the papillary muscle
- Myocardial infarction
Fig. 16.83 Mitral regurgitation: murmur and systolic wave in left atrial pressure. The first sound is normal or soft and merges with a pansystolic murmur (PSM) extending to the second heart sound. A third heart sound occurs with severe regurgitation. A transoesophageal echocardiogram shows mitral valve prolapse, with one leaflet bulging towards the left atrium (LA, arrow). This results in a jet of mitral regurgitation on colour Doppler (arrow).

Mitral valve prolapse
This is also known as ‘floppy’ mitral valve and is a common cause of mild mitral regurgitation (Fig. 16.83). Some cases are thought to be due to a developmental abnormality of the mitral valve and others due to degenerative myxomatous change in a normal mitral valve. Rarely, mitral valve prolapse may occur in association with Marfan’s syndrome (p. 508).

In its mildest forms, the valve remains competent but bulges back into the atrium during systole, causing a mid-systolic click but no murmur. In the presence of a regurgitant valve, the click is followed by a late systolic murmur, which lengthens as the regurgitation becomes more severe. A click is not always audible and the physical signs may vary with both posture and respiration. Progressive elongation of the chordae tendineae leads to increasing mitral regurgitation, and if chordal rupture occurs, regurgitation suddenly becomes severe. This is rare before the fifth or sixth decade of life.

Mitral valve prolapse is associated with a variety of typically benign arrhythmias, atypical chest pain and a very small risk of embolic stroke or transient ischaemic attack (TIA). Nevertheless, the overall long-term prognosis is good.

Other causes of mitral regurgitation
Mitral valve function depends on the chordae tendineae and their papillary muscles; dilatation of the LV distorts the geometry of these and may cause mitral regurgitation (Box 16.80). Dilated cardiomyopathy and heart failure from CAD are common causes of so-called ‘functional’ mitral regurgitation. Endocarditis is an important cause of acute mitral regurgitation.

Clinical features
Symptoms and signs depend on the underlying cause and how suddenly the regurgitation develops (Box 16.81). Chronic mitral regurgitation produces a symptom complex that is similar to that of mitral stenosis but sudden-onset mitral regurgitation usually presents with acute pulmonary oedema.

The regurgitant jet causes an apical systolic murmur (Fig. 16.83), which radiates into the axilla and may be accompanied by a thrill. Increased forward flow through the mitral valve causes a loud third heart sound and even a short mid-diastolic murmur. The apex beat feels active and rocking due to left ventricular volume overload and is usually displaced to the left as a result of left ventricular dilatation.

Investigations
Echocardiography is a pivotal investigation. The severity of regurgitation can be assessed by Doppler and information may also be gained on papillary muscle function and valve prolapse. An ECG should be performed and commonly shows AF, as a consequence of atrial dilatation. Cardiac catheterisation is
patients, because results are excellent and early repair prevents irreversible left ventricular damage. Mitral regurgitation often accompanies left ventricular failure associated with CAD. If such patients are to undergo CABG surgery, it is common practice to repair the valve and restore mitral valve function by inserting an annuloplasty ring to overcome annular dilatation and to bring the valve leaflets closer together. Unfortunately, it can be difficult to determine whether it is the ventricular dilatation or the mitral regurgitation that is the predominant problem. If ventricular dilatation is the underlying cause of mitral regurgitation, then mitral valve repair or replacement may actually worsen ventricular function, as the ventricle can no longer empty into the low-pressure LA.

**Aortic valve disease**

### Aortic stenosis

There are several causes of aortic stenosis but the age at which patients present can give a clue to the most likely diagnosis (Box 16.84). In congenital aortic stenosis, obstruction is present from birth or becomes apparent during infancy. With bicuspid aortic valves, obstruction may take years to develop as the valve becomes fibrotic and calcified, and these patients present as young to middle-aged adults. Rheumatic disease of the aortic valve presents at a similar age but is usually accompanied by mitral valve disease. In older people, structurally normal aortic valves may become stenotic as the result of fibrosis and calcification. Haemodynamically significant stenosis develops slowly, typically occurring at 30–60 years in those with rheumatic disease, 50–60 years in those with bicuspid aortic valves and 70–90 years in those with calcific tricuspid disease.

#### Pathogenesis

Cardiac output is initially maintained in patients with aortic stenosis at the cost of a steadily increasing pressure gradient across the aortic valve. With progression of the stenosis the LV becomes increasingly hypertrophied and coronary blood flow may be inadequate to supply the myocardium, such that

### Causes of aortic stenosis

#### Infants, children, adolescents

- Congenital aortic stenosis
- Congenital subvalvular aortic stenosis
- Congenital supravalvular aortic stenosis

#### Young adults to middle-aged

- Calcification and fibrosis of congenitally bicuspid aortic valve
- Rheumatic aortic stenosis

#### Middle-aged to elderly

- Senile degenerative aortic stenosis
- Calcification of bicuspid valve
- Rheumatic aortic stenosis
Clinical features

Aortic stenosis is commonly picked up in asymptomatic patients at routine clinical examination but the three cardinal symptoms are angina, breathlessness and syncope (Box 16.85). Angina arises either because of the increased demands of the hypertrophied LV working against the high-pressure outflow tract obstruction, or the presence of coexisting CAD, which affects over 50% of patients. Exertional breathlessness suggests cardiac decompensation as a consequence of the excessive pressure overload placed on the LV. Syncope usually occurs on exertion when cardiac output fails to rise to meet demand, leading to a fall in BP. Sometimes patients with severe aortic stenosis do not complain of symptoms. If, on clinical evaluation, this appears to be due to a sedentary lifestyle, a careful exercise test may reveal symptoms on modest exertion.

The characteristic clinical signs of severe aortic stenosis are shown in Box 16.85. A harsh ejection systolic murmur radiates to the neck, with a soft second heart sound, particularly in those with calcific valves. The murmur is often likened to a saw cutting wood and may (especially in older patients) have a musical quality like the ‘mew’ of a seagull (Fig. 16.84). The severity of aortic stenosis may be difficult to gauge clinically, as older patients with a non-compliant ‘stiff’ arterial system may have an apparently normal carotid upstroke in the presence of severe aortic stenosis. Milder degrees of stenosis may be difficult to distinguish from aortic sclerosis, in which the valve is thickened or calcified but not obstructed. A careful examination should be made for other valve lesions, particularly in rheumatic heart disease, when there is frequently concomitant mitral valve disease. In contrast to patients with mitral stenosis, which tends to progress very slowly, patients with aortic stenosis typically remain asymptomatic for many years but deteriorate rapidly when symptoms develop; if otherwise untreated, they usually die within 3–5 years of presentation.

Investigations

Echocardiography is a pivotal investigation in patients suspected of having aortic stenosis. It can demonstrate restricted valve opening (Fig. 16.85) and Doppler assessment permits calculation of the systolic gradient across the aortic valve, from which the severity of stenosis can be assessed (see Fig. 16.11, p. 451). In

---

**Clinical features of aortic stenosis**

**Symptoms**
- Mild or moderate stenosis: usually asymptomatic
- Exertional dyspnoea
- Angina
- Exertional syncope
- Sudden death
- Episodes of acute pulmonary oedema

**Signs**
- Ejection systolic murmur
- Slow-rising carotid pulse
- Thrusting apex beat (left ventricular pressure overload)
- Narrow pulse pressure
- Signs of pulmonary venous congestion

**Fig. 16.84 Aortic stenosis.** Pressure traces show the systolic gradient between left ventricle (LV) and aorta. The ‘diamond-shaped’ murmur is heard best with the diaphragm in the aortic outflow and also at the apex. An ejection click (EC) may be present in young patients with a bicuspid aortic valve but not in older patients with calcified valves. Aortic stenosis may lead to left ventricular hypertrophy with a fourth sound at the apex and post-stenotic dilatation of the aortic arch. Figure 16.11 (p. 451) shows the typical Doppler signal with aortic stenosis.
Diseases of the heart valves

Fig. 16.85 Two-dimensional echocardiogram comparing a normal individual and a patient with calcific aortic stenosis. A Normal individual in diastole; the aortic leaflets are closed and thin, and a point of coaptation is seen (arrow). B Calcific aortic stenosis in diastole; the aortic leaflets are thick and calcified (arrow). C Normal in systole; the aortic leaflets are open (arrows). D Calcific aortic stenosis in systole; the thickened leaflets have barely moved (arrows). From Newby D, Grubb N. Cardiology: an illustrated colour text. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2005.

16.86 Investigations in aortic stenosis

ECG
- Left ventricular hypertrophy
- Left bundle branch block

Chest X-ray
- May be normal; sometimes enlarged left ventricle and dilated ascending aorta on postero-anterior view, calcified valve on lateral view

Echo
- Calcified valve with restricted opening, hypertrophied left ventricle

Doppler
- Measurement of severity of stenosis
- Detection of associated aortic regurgitation

Cardiac catheterisation
- Mainly to identify associated coronary artery disease
- May be used to measure gradient between left ventricle and aorta

Fig. 16.86 Left ventricular hypertrophy. QRS complexes in limb leads have increased amplitude with a very large R wave in V6 and S wave in V2. There is ST depression and T-wave inversion in leads II, III, aVF, V3 and V6: a ‘left ventricular strain’ pattern.

patients with impaired left ventricular function, velocities across the aortic valve may be diminished because of a reduced stroke volume; this is called low-flow aortic stenosis. When marked aortic regurgitation or elevated cardiac output is present, velocities are increased because of an increased stroke volume and this may overestimate stenosis severity on Doppler echocardiography. In advanced cases, ECG features of hypertrophy (Box 16.86) are often pronounced (Fig. 16.86), and down-sloping ST segments
Aortic stenosis in old age

- Incidence: the most common form of valve disease affecting the very old.
- Symptoms: a common cause of syncope, angina and heart failure in the very old.
- Signs: because of increasing stiffening in the central arteries, low pulse pressure and a slow rising pulse may not be present.
- Trans-catheter aortic valve implantation (TAVI): a good option in older individuals because less invasive than surgery.
- Surgery: can be successful in those aged 80 years or more in the absence of comorbidity, but with a higher operative mortality. The prognosis without surgery is poor once symptoms have developed.
- Valve replacement type: a biological valve is often preferable to a mechanical one because this obviates the need for anticoagulation, and the durability of biological valves usually exceeds the patient’s anticipated life expectancy.

Aortic regurgitation

This condition can result from either disease of the aortic valve cusps, infection, trauma or dilatation of the aortic root. The causes are summarised in Box 16.88.

Pathogenesis

Regurgitation of blood through the aortic valve causes the LV to dilate as cardiac output increases to maintain the demands of the circulation. The stroke volume of the LV may eventually be doubled and the major arteries are then conspicuously pulsatile. As the disease progresses, left ventricular failure develops, leading to a rise in left ventricular end-diastolic pressure and pulmonary oedema.

Causes of aortic regurgitation

Congenital
- Bicuspid valve or disproportionate cusps

Acquired
- Rheumatic disease
- Infective endocarditis
- Trauma
- Causes of aortic dilatation:
  - Marfan’s syndrome
  - Aneurysm
  - Aortic dissection
  - Syphilis
  - Ankylosing spondylitis

Clinical features of aortic regurgitation

Symptoms
- Mild to moderate aortic regurgitation
  - Often asymptomatic
  - Palpitations
- Severe aortic regurgitation
  - Breathlessness
  - Angina

Signs
- Pulses
  - Large-volume or ‘collapsing’ pulse
  - Low diastolic and increased pulse pressure
  -Bounding peripheral pulses
- Murmurs
  - Early diastolic murmur
  - Systolic murmur (increased stroke volume)
  - Austin Flint murmur (soft mid-diastolic)

Other signs
- Displaced, heaving apex beat (volume overload)
- Pre-systolic impulse
- Fourth heart sound
- Crepitations (pulmonary venous congestion)

Aortic regurgitation

- Acute severe regurgitation may occur as the result of perforation of an aortic cusp in endocarditis. In this circumstance, there may be no time for compensatory left ventricular hypertrophy and dilatation to develop and the features of heart failure may predominate. The classical signs of aortic regurgitation in such patients may be masked by tachycardia and an abrupt rise in
Diseases of the heart valves

16

Fig. 16.87 Aortic regurgitation. The early diastolic murmur is best heard at the left sternal edge and may be accompanied by an ejection systolic (‘to and fro’) murmur. The aortic arch and left ventricle (LV) may become dilated. The inset shows a Doppler echocardiogram with the regurgitant jet (arrows).

*Not always required.

left ventricular end-diastolic pressure. The pulse pressure may also be normal or near-normal and the diastolic murmur may be short or even absent.

Investigations

Doppler echocardiography is the investigation of first choice for detecting regurgitation (Box 16.90). In severe acute aortic regurgitation, the rapid rise in left ventricular diastolic pressure may cause premature mitral valve closure. Cardiac catheterisation and aortography are usually performed to assess the severity of regurgitation, to determine if there is dilatation of the aorta and to screen for the presence of coexisting CAD. MRI can also be useful in assessing the degree and extent of aortic dilatation if this is suspected on chest X-ray or echocardiography.

Management

Treatment may be required for underlying conditions, such as endocarditis or syphilis. Aortic valve replacement is indicated if aortic regurgitation causes symptoms, and this may need to be combined with aortic root replacement and coronary bypass surgery. Those with chronic aortic regurgitation can remain asymptomatic for many years because compensatory ventricular dilatation and hypertrophy occur, but should be advised to report the development of any symptoms of breathlessness or angina. Asymptomatic patients should also be followed up annually with echocardiography for evidence of increasing ventricular size. If this occurs or if the end-systolic dimension increases to 55 mm or more, then aortic valve replacement should be undertaken. If systemic hypertension is present, vasodilators should be used to control systemic BP. There is conflicting evidence regarding the need for aortic valve replacement in asymptomatic patients with severe aortic regurgitation. When aortic root dilatation is the cause of aortic regurgitation, as can occur in Marfan’s syndrome, aortic root replacement is usually necessary.

Tricuspid valve disease

Tricuspid stenosis

Tricuspid stenosis is usually rheumatic in origin and is rare in developed countries. Tricuspid disease occurs in fewer than 5% of patients with rheumatic heart disease and then nearly always occurs in association with mitral and aortic valve disease. Tricuspid stenosis and regurgitation may also occur in the carcinoid syndrome (p. 678).

Clinical features and investigations

Although the symptoms of mitral and aortic valve disease predominate, tricuspid stenosis may cause symptoms of
right heart failure, including hepatic discomfort and peripheral oedema.

The main clinical feature is a raised JVP with a prominent a wave, and a slow y descent due to the loss of normal rapid right ventricular filling (p. 443). There is also a mid-diastolic murmur, best heard at the lower left or right sternal edge. This is generally higher-pitched than the murmur of mitral stenosis and is increased by inspiration. Right heart failure causes hepatomegaly with pre-systolic pulsation (large a wave), ascites and peripheral oedema. The diagnosis can be confirmed by Doppler echocardiography, which shows similar appearances to those of rheumatic mitral stenosis.

Management
In patients who require surgery to other valves, either the tricuspid valve can also be replaced or treated with valvotomy. Balloon valvuloplasty can be used to treat rare cases of isolated tricuspid stenosis.

Tricuspid regurgitation
Tricuspid regurgitation is common, and is most frequently functional, occurring as a result of right ventricular dilatation due to right heart failure or biventricular failure. It may also be the result of other conditions, as summarised in Box 16.91.

Clinical features
Symptoms are usually non-specific, with tiredness related to reduced cardiac output, and oedema and hepatic enlargement due to venous congestion. The most prominent sign is a ‘giant’ v wave in the jugular venous pulse (a cv wave replaces the normal x descent). Other features include a pansystolic murmur at the left sternal edge and a pulsatile liver. Echocardiography may reveal dilatation of the RV. If the valve has been affected by rheumatic disease, the leaflets will appear thickened and, in endocarditis, vegetations may be seen.

Management
Tricuspid regurgitation due to right ventricular dilatation often improves when the cardiac failure is treated. Patients with a normal pulmonary artery pressure tolerate isolated tricuspid reflux well, and valves damaged by endocarditis do not usually need to be replaced. Patients undergoing mitral valve replacement, who have tricuspid regurgitation due to marked dilatation of the tricuspid annulus, benefit from valve repair with an annuloplasty ring to bring the leaflets closer together. Those with rheumatic damage may require tricuspid valve replacement.

Pulmonary valve disease

Pulmonary stenosis
This can occur in the carcinoid syndrome but is usually congenital, in which case it may be isolated or associated with other abnormalities, such as Fallot’s tetralogy (p. 506).

Clinical features
The principal finding on examination is an ejection systolic murmur, loudest at the left upper sternum and radiating towards the left shoulder. There may be a thrill, best felt when the patient leans forwards and breathes out. The murmur is often preceded by an ejection sound (click). Delay in right ventricular ejection may cause wide splitting of the second heart sound. Severe pulmonary stenosis is characterised by a loud, harsh murmur, an inaudible pulmonary closure sound (P2), an increased right ventricular heave, and prominent a waves in the jugular pulse.

Investigations
Doppler echocardiography is the definitive investigation. ECG may show evidence of right ventricular hypertrophy, and post-stenotic dilatation in the pulmonary artery may be observed on the chest X-ray.

Management
Mild to moderate isolated pulmonary stenosis is relatively common and does not usually progress or require treatment. Severe pulmonary stenosis (resting gradient >50 mmHg with a normal cardiac output) can be treated by percutaneous pulmonary balloon valvuloplasty or, if this is not available, by surgical valvotomy. Long-term results are very good. Post-operative pulmonary regurgitation is common but benign.

Pulmonary regurgitation
This is rare in isolation and is usually associated with pulmonary artery dilatation due to pulmonary hypertension. It may complicate mitral stenosis, producing an early diastolic decrescendo murmur at the left sternal edge that is difficult to distinguish from aortic regurgitation (Graham Steell murmur). The pulmonary hypertension may be secondary to other disease of the left side of the heart, primary pulmonary vascular disease or Eisenmenger’s syndrome (p. 532). Trivial pulmonary regurgitation is a frequent finding in normal individuals and has no clinical significance.

Prosthetic valves
Diseased heart valves can be replaced with mechanical or biological prostheses. The three most commonly used types of mechanical prosthesis are the ball and cage, tilting single disc and tilting bi-leaflet valves. All generate prosthetic sounds or clicks on auscultation. Pig or allograft valves mounted on a supporting stent are the most commonly used biological valves. They generate normal heart sounds. All prosthetic valves used in the aortic position produce a systolic flow murmur.

All mechanical valves require long-term anticoagulation because they can cause systemic thromboembolism or may develop valve thrombosis or obstruction (Box 16.92); the prosthetic clicks may become inaudible if the valve malfunctions. Biological valves have the advantage of not requiring anticoagulants to maintain proper function; however, many patients undergoing valve replacement surgery, especially mitral valve replacement, will have AF that

Transcatheter aortic valve implantation (TAVI): bioprosthetic valve.

Transcatheter aortic valve implantation

For patients being considered for aortic valve surgery, especially due to aortic stenosis, transcatheter aortic valve implantation (TAVI) is an emerging alternative to surgical aortic valve replacement. The native valve is not removed but is compressed by the new bioprosthetic valve, which is implanted within it. The bioprosthetic valve is mounted on a large stent-like structure and is implanted through a catheter inserted in the femoral artery (Fig. 16.88). TAVI has several major advantages. It avoids the need for a sternotomy, is associated with a short recovery period, can be used in high-risk and otherwise inoperable patients, and is much better tolerated by elderly patients. Complications include stroke (2%) and heart block necessitating pacemaker implantation (5–15%).

Prosthetic valve dysfunction

Symptoms or signs of unexplained heart failure in a patient with a prosthetic heart valve may be due to valve dysfunction, and urgent assessment is required. Metallic valves can suffer strut fracture and fail, causing catastrophic regurgitation. Alternatively, they may thrombose and cause systemic thromboembolism or valve obstruction, especially in the presence of inadequate anticoagulation. Biological valve dysfunction is usually associated with the development of a regurgitant murmur and may begin to develop 8–10 years after implantation.

Infective endocarditis

This is caused by microbial infection of a heart valve, the lining of a cardiac chamber or blood vessel, or by a congenital anomaly. Both native and prosthetic valves can be affected. The most common causes of infective endocarditis are streptococci and staphylococci but other organisms may also be involved.

Epidemiology

The incidence of infective endocarditis in community-based studies ranges from 5 to 15 cases per 100 000 per annum. More than 50% of patients are over 60 years of age (Box 16.93). In a large British study, the underlying condition was rheumatic heart disease in 24% of patients, congenital heart disease in 19%, and other cardiac abnormalities such as calcified aortic valve or floppy mitral valve in 25%. The remaining 32% were not thought to have a pre-existing cardiac abnormality. Bacterial endocarditis is a serious illness; the case fatality is approximately 20% even with treatment, and is even higher in those with prosthetic valve endocarditis and those infected with antibiotic-resistant organisms.

Pathophysiology

Infective endocarditis typically occurs at sites of pre-existing endocardial damage, but infection with particularly virulent or aggressive organisms such as Staphylococcus aureus can cause endocarditis in a previously normal heart. Staphylococcal endocarditis of the tricuspid valve is a common complication of intravenous drug use. Many acquired and congenital cardiac lesions are vulnerable, particularly areas of endocardial damage caused by a high-pressure jet of blood, such as ventricular septal defect, mitral regurgitation and aortic regurgitation, many of which are haemodynamically insignificant. In contrast, the risk of endocarditis at the site of haemodynamically important low-pressure lesions, such as a large atrial septal defect, is minimal.

Infection tends to occur at sites of endothelial damage because they attract deposits of platelets and fibrin that are vulnerable to colonisation by blood-borne organisms. The avascular valve tissue and presence of fibrin and platelet aggregates help to protect proliferating organisms from host defence mechanisms. When the infection is established, vegetations composed of organisms, fibrin and platelets grow and may become large enough to cause obstruction or embolism. Adjacent tissues are destroyed and abscesses may form. Valve regurgitation may develop or increase if the affected valve is damaged by tissue distortion, cusp perforation or disruption of chordae. Extracardiac manifestations, such as vasculitis and skin lesions, may occur as the result of either emboli or immune complex deposition. Mycotic aneurysms may develop in arteries at the site of infected emboli. In fatal cases, infarction of the spleen and kidneys and, sometimes, an immune glomerulonephritis may be found at postmortem.

Common causative organisms

- **Streptococcus gallolyticus subsp. gallolyticus** (from a colonic source).
- **Staphylococcus aureus**.
- **Streptococcus viridans**.
- **Actinomyces israelii**.
- **Mycoplasma hominis**.

**16.93 Endocarditis in old age**

- **Symptoms and signs**: may be non-specific, with delirium, weight loss, malaise and weakness, and the diagnosis may not be suspected.
- **Common causative organisms**: often enterococci (from the urinary tract) and *Streptococcus gallolyticus* subsp. *gallolyticus* (from a colonic source).
- **Morbidity and mortality**: much higher.
Microbiology

Over three-quarters of cases are caused by streptococci or staphylococci. Viridans streptococci, such as Streptococcus mitis and Strep. sanguis, which are commensals in the oral cavity, can enter the bloodstream on chewing or tooth-brushing, or at the time of dental treatment, and are common causes of subacute endocarditis (Box 16.94). Other organisms, including Enterococcus faecalis, E. faecium and Strep. gallolyticus subsp. gallolyticus (previously known as Strep. bovis), may enter the blood from the bowel or urinary tract. Patients who are found to have endocarditis caused by Strep. gallolyticus should undergo colonoscopy, since this organism is associated with large-bowel malignancy.

Staph. aureus has now overtaken streptococci as the most common cause of acute endocarditis. It originates from skin infections, abscesses or vascular access sites such as intravenous and central lines, or from intravenous drug use. It is highly virulent and invasive, usually producing florid vegetations, rapid valve destruction and abscess formation. Other causes of acute endocarditis include Strep. pneumoniae and Strep. pyogenes.

Post-operative endocarditis after cardiac surgery may affect native or prosthetic heart valves or other prosthetic materials. The most common organisms are coagulase-negative staphylococci and coagulase-negative staphylococci such as Staph. epidermidis, which are part of the normal skin flora. There is frequently a history of wound infection with the same organism. Coagulase-negative staphylococci cause native valve endocarditis in approximately 5% of cases and this possibility should always be considered before they are dismissed as blood culture contaminants. Another coagulase-negative staphylococcus, Staph. lugdunensis, causes a rapidly destructive acute endocarditis that is associated with previously normal valves and multiple emboli. Unless accurately identified, it may also be overlooked as a contaminant.

In Q fever endocarditis due to Coxiella burnetii, the patient often has a history of contact with farm animals. The aortic valve is usually affected and there may also be hepatitis, pneumonia and purpura. Life-long antibiotic therapy may be required.

In about 3–4% of cases, endocarditis may be caused by Gram-negative bacteria of the so-called HACEK group (Haemophilus aphrophilus – now known as Aggregatibacter aphrophilus–Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis; Eikenella corrodens; and Kingella kingae). These are slow-growing, fastidious Gram-negative organisms that are oropharyngeal commensals. The diagnosis may be revealed only after prolonged culture and the organisms may be resistant to penicillin.

Brucella endocarditis is associated with a history of contact with goats or cattle and often affects the aortic valve.

Yeasts and fungi, such as Candida and Aspergillus, may attack previously normal or prosthetic valves, particularly in immunocompromised patients or those with in-dwelling intravenous catheters. Abscesses and emboli are common, therapy is difficult, surgery is often required and mortality is high. Concomitant bacterial infection may be present.

Clinical features

Endocarditis can take either an acute or a more insidious ‘subacute’ form. There is considerable overlap, however, because the clinical pattern is influenced not only by the organism but also by the site of infection, prior antibiotic therapy and the presence of a valve or shunt prosthesis. The subacute form may abruptly develop acute life-threatening complications, such as valve disruption or emboli. The Duke criteria for diagnosis of infective endocarditis are shown in Box 16.95.

Subacute endocarditis

This should be suspected when a patient with congenital or valvular heart disease develops a persistent fever, complains of unusual tiredness, night sweats or weight loss, or develops new signs of valve dysfunction or heart failure. Less often, it presents as an embolic stroke or peripheral arterial embolism. Other features (Fig. 16.89) include purpura and petechial haemorrhages in the skin and mucous membranes, and splinter haemorrhages under the fingernails or toenails. Osler’s nodes are painful, tender swellings at the fingertips that are probably the product of vasculitis; they are rare. Digital clubbing is a late sign. The spleen is frequently palpable; in Coxiella infections, the spleen and the

HACEK = Haemophilus aphrophilus – now known as Aggregatibacter aphrophilus–Aggregatibacter actinomycetemcomitans; Cardiobacterium hominis; Eikenella corrodens; and Kingella kingae. Adapted from Moreillon P, Due YA. Infective endocarditis. Lancet 2004; 363:139–149.
Diagnosis of infective endocarditis

**Major criteria**
- **Positive blood culture**
  - Typical organism from two cultures
  - Persistent positive blood cultures taken >12 hrs apart
  - Three or more positive cultures taken over >1 hr

**Cardiac involvement**
- Positive echocardiographic findings of vegetations
- New valvular regurgitation

**Minor criteria**
- Predisposing valvular or cardiac abnormality
- Intravenous drug misuse
- Pyrexia ≥38°C
- Embolic phenomenon
- Vasculitic phenomenon
- Blood cultures suggestive: organism grown but not achieving major criteria
- Suggestive echocardiographic findings

*Modified Duke criteria. Patients with two major, or one major and three minor, or five minor have definite endocarditis. Patients with one major and one minor, or three minor have possible endocarditis.

Liver may be considerably enlarged. Non-visible haematuria is common. The finding of any of these features in a patient with persistent fever or malaise is an indication for re-examination to detect hitherto unrecognised heart disease.

**Acute endocarditis**
This presents as a severe febrile illness with prominent and changing heart murmurs and petechiae. Clinical stigmata of chronic endocarditis are usually absent. Embolic events are common, and cardiac or renal failure may develop rapidly. Abscesses may be detected on echocardiography. Partially treated acute endocarditis behaves like subacute endocarditis.

**Post-operative endocarditis**
This may present as an unexplained fever in a patient who has had heart valve surgery. The infection usually involves the valve ring and may resemble subacute or acute endocarditis, depending on the virulence of the organism. Morbidity and mortality are high and revision surgery is often required. The range of organisms is similar to that seen in native valve disease, but when endocarditis occurs during the first few weeks after surgery it is usually due to infection with a coagulase-negative staphylococcus that was introduced during the perioperative period.
Proteinuria may occur and non-visible haematuria is usually present. Serum CRP is more reliable than the ESR in monitoring progress. Detecting abscess formation does not exclude the diagnosis. Approximately 65% but that of TOE is more than 90%. Failure to detect vegetations does not exclude the diagnosis. Vegetations may be difficult to distinguish in the presence of an abnormal valve; the sensitivity of transthoracic echocardiography is smaller ones (1–1.5 mm) can be visualised by trans-oesophageal echocardiography (TOE), which is particularly valuable for identifying abscess formation and investigating patients with prosthetic heart valves. Vegetations may be difficult to distinguish in the presence of an abnormal valve; the sensitivity of transthoracic echo is approximately 65% but that of TOE is more than 90%. Failure to detect vegetations does not exclude the diagnosis.

Elevation of the ESR, a normocytic normochromic anaemia, and leucocytosis are common but not invariable. Measurement of serum CRP is more reliable than the ESR in monitoring progress. Proteinuria may occur and non-visible haematuria is usually present.

**Investigations**

Blood culture (see Fig. 6.6, p. 107) is the pivotal investigation to identify the organism that is the cause of the infection and to guide antibiotic therapy. Three to six sets of blood cultures should be taken prior to commencing therapy and should not wait for episodes of pyrexia. The first two specimens will detect bacteraemia in 90% of culture-positive cases. A meticulous aseptic technique is essential. Taking discrete sets of blood cultures from peripheral sites at intervals of 6 hours reduces the risk of misdiagnosis due to contamination with skin commensals. Isolation of a typical organism in more than one culture provides strong evidence in favour of the diagnosis (Box 16.95). An indwelling line should not be used to take cultures. Both aerobic and anaerobic cultures are required.

Echocardiography is key for detecting and following the progress of vegetations, for assessing valve damage and for detecting abscess formation. Vegetations as small as 2–4 mm can be detected by transthoracic echocardiography, and even smaller ones (1–1.5 mm) can be visualised by trans-oesophageal echocardiography (TOE), which is particularly valuable for identifying abscess formation and investigating patients with prosthetic heart valves. Vegetations may be difficult to distinguish in the presence of an abnormal valve; the sensitivity of transthoracic echo is approximately 65% but that of TOE is more than 90%. Failure to detect vegetations does not exclude the diagnosis.

Elevation of the ESR, a normocytic normochromic anaemia, and leucocytosis are common but not invariable. Measurement of serum CRP is more reliable than the ESR in monitoring progress. Proteinuria may occur and non-visible haematuria is usually present.

The ECG may show the development of AV block (due to aortic root abscess formation) and occasionally infarction due to emboli. The chest X-ray may show evidence of cardiac failure and cardiomegaly.

**Management**

A multidisciplinary approach, with cooperation between the physician, surgeon and microbiologist, increases the chance of a successful outcome. Any source of infection should be removed as soon as possible; for example, a tooth with an apical abscess should be extracted.

Empirical treatment depends on the mode of presentation, the suspected organism and the presence of a prosthetic valve or penicillin allergy. If the presentation is subacute, antibiotic treatment should ideally be withheld until the results of blood cultures are available. However, if empirical antibiotic treatment is considered necessary, amoxicillin (2 g 6 times daily IV) should be considered (with or without gentamicin). If the presentation is acute, empirical therapy should be started with vancomycin (1 g twice daily IV) and gentamicin (1 mg/kg twice daily IV) with dose adjustment based on antibiotic levels. The same regimen is used in true penicillin allergy. Patients with suspected prosthetic valve endocarditis should be treated with vancomycin and gentamicin at the above-mentioned doses, plus rifampicin orally in a dose of 300–600 mg twice daily. Following identification of the causal organism, determination of the minimum inhibitory concentration (MIC) for the organism helps guide antibiotic therapy. Recommended regimens for some of the most common scenarios are shown in Box 16.96. More detailed information

1When conditions in Box 16.97 are met, 2 weeks of benzylpenicillin and gentamicin (1 mg/kg twice daily) may be sufficient. Ceftriaxone 2 g once daily IV/IM can be used instead of benzylpenicillin for those with non-severe penicillin allergy. 2Pre-dose gentamicin level should be ≤ 8 mg/L. Post-dose 3–5 mg/L. Adjust dose according to levels and renal function. 3Pre-dose vancomycin level should be 15–20 mg/L. Adjust dose according to levels and renal function. 4Use 6 times daily if weight > 85 kg. (IV = intravenous; MIC = minimum inhibitory concentration)

Congenital heart disease

Congenital heart disease can be the result of defects in the formation of the heart or great vessels or can arise because of abnormalities in the anatomical changes that occur during transition between the fetus and the newborn child fail to proceed normally. Congenital heart disease usually presents in childhood but some patients do not present until adult life. It has been estimated that the incidence of haemodynamically significant congenital cardiac abnormalities is about 0.8% of live births (Box 16.99). Defects that are well tolerated, such as atrial septal defect, may cause no symptoms until adult life or may be detected incidentally on routine examination or chest X-ray. Congenital defects that were previously fatal in childhood can now be corrected, or at least partially, so that survival to adult life is the norm. Such patients remain well for many years but subsequently re-present in later life with related problems such as arrhythmia or heart failure (Box 16.100).

Pathophysiology

Understanding the fetal circulation helps clarify how some forms of congenital heart disease occur. Figure 16.90 shows the fetal circulation and the changes that normally occur immediately after birth. In the fetus there is little blood flow through the lungs, which are collapsed because they are not required for gas exchange. Instead, oxygenated blood from the placenta passes directly from the right atrium to the left side of the heart through the foramen ovale without having to flow through the lungs, and also from the pulmonary artery into the aorta via the ductus arteriosus.

During early embryonic life, the heart develops as a single tube that folds back on itself and then divides into two separate circulations. Failure of septation can cause some forms of atrial and ventricular septal defect, whereas failure of alignment of the great vessels with the ventricles contributes to transposition of the great arteries, tetralogy of Fallot and truncus arteriosus. Atrial septal defects occur because the foramen ovale fails to close at birth, as is normal. Similarly, a persistent ductus arteriosus will remain persistent if it fails to close after birth. Failure of the aorta to develop at the point of the aortic isthmus and where the ductus arteriosus attaches can lead to coarctation of the aorta. Maternal infection and exposure to drugs or toxins are important causes of congenital heart disease. Maternal rubella infection is associated with persistent ductus arteriosus, pulmonary valvular...
Fig. 16.90 Changes in the circulation at birth. **A** In the fetus, oxygenated blood comes through the umbilical vein where it enters the inferior vena cava (IVC) via the ductus venosus (red). The oxygenated blood streams from the right atrium (RA) through the open foramen ovale to the left atrium (LA) and via the left ventricle (LV) into the aorta. Venous blood from the superior vena cava (SVC, blue) crosses under the main blood stream into the RA and then, partly mixed with oxygenated blood (purple), into the right ventricle (RV) and pulmonary artery (PA). The pulmonary vasculature has a high resistance and so little blood passes to the lungs; most blood passes through the ductus arteriosus to the descending aorta. The aortic isthmus is a constriction in the aorta that lies in the aortic arch before the junction with the ductus arteriosus and limits the flow of oxygen-rich blood to the descending aorta. This configuration means that less oxygen-rich blood is supplied to organ systems that take up their function mainly after birth, e.g. the kidneys and intestinal tract. **B** At birth, the lungs expand with air and pulmonary vascular resistance falls, so that blood now flows to the lungs and back to the LA. The left atrial pressure rises above right atrial pressure and the flap valve of the foramen ovale closes. The umbilical arteries and the ductus venosus close. In the next few days, the ductus arteriosus closes under the influence of hormonal changes (particularly prostaglandins) and the aortic isthmus expands. (PV = pulmonary vein) Adapted from Drews U. Colour atlas of embryology. Stuttgart: Georg Thieme; 1995.

and/or artery stenosis, and atrial septal defect. Maternal alcohol misuse is associated with septal defects, and maternal lupus erythematosus with congenital complete heart block. Genetic or chromosomal abnormalities, such as Down’s syndrome, may cause septal defects, and gene defects have also been identified as leading to specific abnormalities, such as Marfan’s syndrome (p. 508) and DiGeorge’s syndrome (deletion in chromosome 22q).

**Clinical features**

Symptoms may be absent, or the child may be breathless or fail to attain normal growth and development. Some defects are not compatible with extrauterine life and lead to neonatal death. Clinical signs vary with the anatomical lesion. Murmurs, thrills or signs of cardiomegaly may be present. In coarctation of the aorta, radio-femoral delay may be noted (Fig. 16.91) and some female patients have the features of Turner’s syndrome (p. 659). Features of other congenital conditions, such as Marfan’s syndrome or Down’s syndrome, may also be apparent. Cerebrovascular events and cerebral abscesses may complicate severe cyanotic congenital disease.

Early diagnosis is important because many types of congenital heart disease are amenable to surgery, but this opportunity is lost if secondary changes, such as irreversible pulmonary hypertension, occur.

**Central cyanosis and digital clubbing**

Central cyanosis of cardiac origin occurs when desaturated blood enters the systemic circulation without passing through the lungs (right-to-left shunting). In the neonate, the most common cause is transposition of the great arteries, in which the aorta arises from the RV and the pulmonary artery from the LV in association with a ventricular septal defect. In older children, cyanosis is usually the consequence of a ventricular septal defect combined with severe pulmonary stenosis (as in tetralogy of Fallot) or with pulmonary vascular disease (Eisenmenger’s syndrome). Prolonged cyanosis is associated with finger and toe clubbing (p. 442).
Growth retardation and learning difficulties
These may occur with large left-to-right shunts at ventricular or
great arterial level, and also with other defects, especially if they
form part of a genetic syndrome. Major intellectual impairment
is uncommon in children with isolated congenital heart disease;
minor learning difficulties can occur, however. Cerebral function
can also be affected after cardiac surgery if cerebral perfusion
is compromised.

Syncope
In the presence of increased pulmonary vascular resistance
or severe left or right ventricular outflow obstruction, exercise
may provoke syncope as systemic vascular resistance falls
but pulmonary vascular resistance rises, worsening right-to-left
shunting and cerebral oxygenation. Syncope can also occur
because of associated arrhythmias.

Pulmonary hypertension
Persistently raised pulmonary flow with a left-to-right shunt causes
increased pulmonary vascular resistance followed by pulmonary
hypertension. Progressive changes, including obliteration of
distal arterioles, take place and are irreversible. At this stage,
central cyanosis occurs and digital clubbing develops. The chest
X-ray shows enlarged central pulmonary arteries and peripheral
‘pruning’ of the pulmonary vessels. The ECG shows features of
right ventricular hypertrophy.

Eisenmenger’s syndrome
In patients with severe and prolonged pulmonary hypertension
the left-to-right shunt may reverse, resulting in right-to-left shunt
and marked cyanosis. This is termed Eisenmenger’s syndrome. The
cyanosis in Eisenmenger’s syndrome may be more apparent
in the feet and toes than in the upper part of the body, resulting
in so-called differential cyanosis. Eisenmenger’s syndrome is
more common with large ventricular septal defects or persistent
ductus arteriosus than with atrial septal defects. Patients with
Eisenmenger’s syndrome are at particular risk from abrupt
changes in afterload that exacerbate right-to-left shunting, such
as vasodilatation, anaesthesia and pregnancy.

Congenital heart disease in pregnancy
During pregnancy, there is a 50% increase in plasma volume, a
40% increase in whole blood volume and a similar increase in
cardiac output, so problems may arise in women with congenital
heart disease (Box 16.101). Many with palliated or untreated
disease will tolerate pregnancy well, however. Pregnancy is
particularly hazardous in the presence of conditions associated
with cyanosis or severe pulmonary hypertension; maternal mortality
in patients with Eisenmenger’s syndrome is more than 50%.

16.101 Pregnancy in women with congenital
heart disease
- Obstructive lesions: poorly tolerated and associated with
  significant maternal morbidity and mortality.
- Cyanotic conditions: especially poorly tolerated. Specialised
  pre-conception counselling should explain the increased risks.
- Surgically corrected disease: patients often tolerate
  pregnancy well.
- Children of patients with congenital heart disease: 2–5% will
  be born with cardiac abnormalities, especially if the mother is
  affected. The risk may be up to 20% in babies born of women with
  left-sided lesions.

### Persistent ductus arteriosus

Normally, the ductus arteriosus closes soon after birth but in
this anomaly it fails to do so. Persistence of the ductus is often
associated with other abnormalities and is more common in
females.

**Pathophysiology**

During fetal life, before the lungs begin to function, most of the
blood from the pulmonary artery passes through the ductus
arteriosus into the aorta (see Fig. 16.90). Persistence of the
ductus causes a continuous AV shunt from the aorta to the
pulmonary artery since pressure in the aorta is higher than
that in the pulmonary circulation. The volume of the shunt
depends on the size of the ductus but as much as 50% of the
left ventricular output may be recirculated through the lungs,
with a consequent increase in the work of the heart (Fig. 16.92).
A large left-to-right shunt in infancy may cause a considerable
rise in pulmonary artery pressure and sometimes this leads to
progressive pulmonary vascular damage.

**Clinical features**

With small shunts there may be no symptoms for years, but
when the ductus is large, growth and development may be
retarded. Usually, there is no disability in infancy but cardiac
failure may eventually ensue, dyspnoea being the first symptom.
A continuous ‘machinery’ murmur is heard with late systolic
accentuation, maximal in the second left intercostal space below
the clavicle (Fig. 16.92). It is frequently accompanied by a thrill.
Pulses are increased in volume.

Enlargement of the pulmonary artery may be detected
radiologically. The ECG is usually normal. If pulmonary vascular
resistance increases, pulmonary artery pressure may rise until it
equals or exceeds aortic pressure. The shunt through the defect

![Persistent ductus arteriosus. There is a connection between the aorta and the pulmonary artery with left-to-right shunting. (LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle)](image)
may then reverse, causing Eisenmenger’s syndrome. The murmur becomes quieter, may be confined to systole or may disappear.

**Investigations**

Echocardiography is the investigation of choice although the persistent ductus requires specific echocardiographic views, such as from the suprasternal notch, to reveal it. The ECG shows evidence of right ventricular hypertrophy.

**Management**

A persistent ductus can be closed at cardiac catheterisation with an implantable occlusive device. Closure should be undertaken in infancy if the shunt is significant and pulmonary resistance not elevated, but this may be delayed until later childhood in those with smaller shunts, for whom closure remains advisable to reduce the risk of endocarditis. When the ductus is structurally intact, a prostaglandin synthetase inhibitor (indometacin or ibuprofen) may be used in the first week of life to induce closure. However, in the presence of a congenital defect with impaired lung perfusion, such as occurs in severe pulmonary stenosis and left-to-right shunt through the ductus, it may be advisable to improve oxygenation by keeping the ductus open with prostaglandin treatment. Unfortunately, these treatments do not work if the ductus is intrinsically abnormal.

### Coarctation of the aorta

This condition is twice as common in males and occurs in 1 in 4000 children. It is associated with other abnormalities, most frequently bicuspid aortic valve and ‘berry’ aneurysms of the cerebral circulation (p. 1160). Acquired coarctation of the aorta is rare but may follow trauma or occur as a complication of a progressive arteritis (Takayasu’s disease, p. 1041).

**Pathogenesis**

Narrowing of the aorta occurs in the region where the ductus arteriosus joins the aorta, at the isthmus just below the origin of the left subclavian artery (see Fig. 16.90). This causes raised BP affecting vessels of the head and neck proximal to the coarctation, and reduced BP and impaired circulation distally.

**Clinical features**

Aortic coarctation is an important cause of cardiac failure in the newborn but symptoms are often absent in older children or adults. Headaches may occur from hypertension proximal to the coarctation, and occasionally weakness or cramps in the legs may result from decreased circulation in the lower part of the body. The BP is raised in the upper body but normal or low in the legs. The femoral pulses are weak and delayed in comparison with the radial pulse (see Fig. 16.91). A systolic murmur is usually heard posteriorly, over the coarctation. There may also be an ejection click and systolic murmur in the aortic area due to a bicuspid aortic valve. As a result of the aortic narrowing, collaterals form; they mainly involve the periscapular, internal mammary and intercostal arteries, and may result in localised bruits.

**Investigations**

Imaging by MRI is the investigation of choice (Fig. 16.93). The chest X-ray in early childhood is often normal but later may show changes in the contour of the aorta (indentation of the descending aorta, ‘3 sign’) and notching of the under-surfaces of the ribs from collaterals. The ECG may show evidence of left ventricular hypertrophy, which can be confirmed by echocardiography.

![MRI scan of coarctation of the aorta](image.png)

*Fig. 16.93* MRI scan of coarctation of the aorta. The aorta is severely narrowed just beyond the arch at the start of the descending aorta (arrow A). Extensive collaterals have developed; a large internal mammary artery (arrow B) and several intercostal arteries (arrows C) are shown. Unusually, in this case, there is also a coarctation of the abdominal aorta (arrow D).

**Management**

In untreated cases, death may occur from left ventricular failure, dissection of the aorta or cerebral haemorrhage. Surgical correction is advisable in all but the mildest cases. If this is carried out sufficiently early in childhood, persistent hypertension can be avoided. Patients repaired in late childhood or adult life often remain hypertensive or develop recurrent hypertension later on. Recurrence of stenosis may occur as the child grows and this may be managed by balloon dilatation and sometimes stenting. The latter may be used as the primary treatment. Coexistent bicuspid aortic valve, which occurs in over 50% of cases, may lead to progressive aortic stenosis or regurgitation, and also requires long-term follow-up.

### Atrial septal defect

Atrial septal defect is one of the most common congenital heart defects and occurs twice as frequently in females. Most are ‘ostium secundum’ defects, involving the fossa ovalis that, in utero, was the foramen ovale (see Fig. 16.90). “Ostium primum” defects result from a defect in the atrioventricular septum and are associated with a ‘cleft mitral valve’ (split anterior leaflet).

**Pathogenesis**

Since the normal RV is more compliant than the LV, a patent foramen ovale is associated with shunting of blood from the LA to the RA, and then to the RV and pulmonary arteries (Fig. 16.94). As a result, there is gradual enlargement of the right side of the heart and of the pulmonary arteries. Pulmonary hypertension and shunt reversal sometimes complicate atrial septal defect, but are less common and tend to occur later in life than with other types of left-to-right shunt.

**Clinical features**

Most children are asymptomatic for many years and the condition is often detected at routine clinical examination or following a chest X-ray. Symptoms that can occur include dyspnoea, chest infections,
Severe pulmonary hypertension and shunt reversal are both contraindications to surgery.

Ventricular septal defect

Ventricular septal defect is the most common congenital cardiac defect, occurring once in 500 live births. The defect may be isolated or part of complex congenital heart disease.

Pathogenesis

Congenital ventricular septal defect occurs as a result of incomplete septation of the ventricles. Embryologically, the interventricular septum has a membranous and a muscular portion, and the latter is further divided into inflow, trabecular and outflow portions. Most congenital defects are ‘perimembranous’, occurring at the junction of the membranous and muscular portions of the septum.

Clinical features

Flow from the high-pressure LV to the low-pressure RV during systole produces a pansystolic murmur, usually heard best at the left sternal edge but radiating all over the precordium (Fig. 16.97). A small defect often produces a loud murmur (maladie de Roger) in the absence of other haemodynamic disturbance. Conversely, a large defect produces a softer murmur.
syndrome, in which case heart–lung transplantation is the only effective treatment. The long-term prognosis is generally very good. An exception is in Eisenmenger’s syndrome, when death normally occurs in the second or third decade of life, but a few individuals survive to the fifth decade without transplantation.

### Tetralogy of Fallot

This is complex defect consisting of right ventricular outflow tract obstruction and right ventricular hypertrophy, a large ventricular septal defect and an over-riding aorta that, when combined with the septal defect, allows blood to be pumped directly from the RV into the aorta. It occurs in about 1 in 2000 births and is the most common cause of cyanosis in infancy after the first year of life.

**Pathogenesis**

Tetralogy of Fallot occurs as the result of abnormal development of the bulbar septum that separates the ascending aorta from the pulmonary artery, and which normally aligns and fuses with the outflow part of the interventricular septum. The right ventricular outflow obstruction is most often subvalvular (infundibular) but may be valvular, supra-valvular or a combination of these (Fig. 16.98). The subvalvular component of the right ventricular outflow obstruction is dynamic and may increase suddenly under adrenergic stimulation. The ventricular septal defect is usually large and similar in aperture to the aortic orifice. The combination results in elevated right ventricular pressure and right-to-left shunting of cyanotic blood across the ventricular septal defect into the aorta.

**Investigations**

Doppler echocardiography should be performed since it helps to identify the small septal defects that are not haemodynamically significant and are likely to close spontaneously. Patients with larger defects should be monitored by serial ECG and echocardiography to screen for signs of pulmonary hypertension. With larger defects, the chest X-ray shows pulmonary congestion and the ECG shows bilateral ventricular hypertrophy.

**Management**

Small ventricular septal defects require no specific treatment. If there is cardiac failure in infancy, this should initially be treated medically with digoxin and diuretics. Persisting failure is an indication for surgical repair of the defect. Percutaneous closure devices are under development.

If serial ECG and echocardiography suggest that pulmonary hypertension is developing, surgical repair should be performed. Surgical closure is contraindicated in fully developed Eisenmenger’s
Clinical features

Children are usually cyanosed but this may not be the case in the neonate because it is only when right ventricular pressure rises to equal or exceed left ventricular pressure that a large right-to-left shunt develops. The affected child may suddenly become increasingly cyanosed, often after feeding or a crying attack, and may become apnoeic and unconscious. These attacks are called ‘Fallot’s spells’. In older children, Fallot’s spells are uncommon but cyanosis becomes increasingly apparent, with stunting of growth, digital clubbing and polycythaemia. Some children characteristically obtain relief by squatting after exertion, which increases the afterload of the left heart and reduces the right-to-left shunting. This is called Fallot’s sign. The natural history before the development of surgical correction was variable but most patients died in infancy or childhood.

On examination, the most characteristic feature is the combination of cyanosis with a loud ejection systolic murmur in the pulmonary area (as for pulmonary stenosis). Cyanosis may be absent in the newborn or in patients with only mild right ventricular outflow obstruction, however. This is called acyanotic tetralogy of Fallot.

Investigations

Echocardiography is diagnostic and demonstrates that the aorta is not continuous with the anterior ventricular septum. The ECG shows right ventricular hypertrophy and the chest X-ray shows an abnormally small pulmonary artery and a ‘boot-shaped’ heart.

Management

The definitive management is total correction of the defect by surgical relief of the pulmonary stenosis and closure of the ventricular septal defect. Primary surgical correction may be undertaken prior to the age of 5 years. If the pulmonary arteries are too hypoplastic, then palliation in the form of a Blalock–Taussig shunt may be performed, with an anastomosis created between the pulmonary artery and subclavian artery. This improves pulmonary blood flow and pulmonary artery development, and may facilitate later definitive correction.

The prognosis after total correction is good, especially if the operation is performed in childhood. Follow-up is needed to identify residual shunting, recurrent pulmonary stenosis and arrhythmias. An implantable defibrillator is sometimes recommended in adulthood.

Other causes of cyanotic congenital heart disease

There are other causes of cyanotic congenital heart disease, as summarised in Box 16.102. Echocardiography is usually the definitive diagnostic procedure, supplemented, if necessary, by cardiac catheterisation.

Adult congenital heart disease

There are increasing numbers of children who have had surgical correction of congenital defects and who may have further problems as adults. The transition period between paediatric and adult care needs to be managed in a carefully planned manner, addressing many diverse aspects of care (Box 16.103). Those who have undergone correction of coarctation of the aorta may develop hypertension in adult life. Those with transposition of the great arteries who have had a ‘Mustard’ repair, in which blood is redirected at atrial level leaving the RV connected to the aorta, may develop right ventricular failure in adult life. This is because the RV is unsuited for function at systemic pressures and may begin to dilate and fail when patients are in their twenties or thirties.

16.102 Other causes of cyanotic congenital heart disease

- Patients: a heterogeneous population with residual disease and sequelae that vary according to the underlying lesion and in severity, each patient must be assessed individually.
- Management plan: should be agreed with the patient and include short- and long-term goals and timing of transition to adult care.
- Risks of surgery: non-cardiac surgery for associated congenital abnormalities carries increased risks and needs to be planned, with careful pre-operative assessment. Risks include thrombosis, embolism from synthetic shunts or patches, and volume overload from fluid shifts. Operative approaches should address cosmetic concerns, such as site of implantation of abdominal generator.
- Exercise: patients with mild or repaired defects can undertake moderately vigorous exercise but those with complex defects, cyanosis, ventricular dysfunction or arrhythmias require specialist evaluation and individualised advice regarding exercise.
- Genetics: Between 10% and 15% have a genetic basis and this should be assessed to understand the impact it may have for the patient’s own future children. A family history, genetic evaluation of syndromic versus non-syndromic disorders and, sometimes, cytogenetics are required.
- Education and employment: may be adversely affected and occupational activity levels need to be assessed.
- End of life: some adolescents with complex disorders may misperceive and think they have been cured; transition to adult services may be the first time they receive information about mortality. Expectations on life expectancy need to be managed and adolescents are often willing to engage with this and play a role in decision-making.

16.103 Congenital heart disease in adolescence

- Patients: a heterogeneous population with residual disease and sequelae that vary according to the underlying lesion and in severity, each patient must be assessed individually.
- Management plan: should be agreed with the patient and include short- and long-term goals and timing of transition to adult care.
- Risks of surgery: non-cardiac surgery for associated congenital abnormalities carries increased risks and needs to be planned, with careful pre-operative assessment. Risks include thrombosis, embolism from synthetic shunts or patches, and volume overload from fluid shifts. Operative approaches should address cosmetic concerns, such as site of implantation of abdominal generator.
- Exercise: patients with mild or repaired defects can undertake moderately vigorous exercise but those with complex defects, cyanosis, ventricular dysfunction or arrhythmias require specialist evaluation and individualised advice regarding exercise.
- Genetics: Between 10% and 15% have a genetic basis and this should be assessed to understand the impact it may have for the patient’s own future children. A family history, genetic evaluation of syndromic versus non-syndromic disorders and, sometimes, cytogenetics are required.
- Education and employment: may be adversely affected and occupational activity levels need to be assessed.
- End of life: some adolescents with complex disorders may misperceive and think they have been cured; transition to adult services may be the first time they receive information about mortality. Expectations on life expectancy need to be managed and adolescents are often willing to engage with this and play a role in decision-making.
Those who have had surgery involving the atria may develop atrial arrhythmias, and those who have ventricular scars may develop ventricular arrhythmias and need consideration for placement of an ICD. Such patients require careful follow-up from the teenage years throughout adult life, so that problems can be identified early and appropriate medical or surgical treatment instituted. The management of patients with grown-up congenital heart disease (GUCH) is complex and has developed as a cardiological subspecialty.

Diseases of the myocardium

Although the myocardium is involved as the result of ischaemia in CAD and in valvular heart disease, this section focuses on conditions that primarily affect the heart muscle.

Myocarditis

This is an acute inflammatory condition that can have an infectious, toxic or autoimmune aetiology (Box 16.104). Myocarditis can complicate many infections in which inflammation may be due directly to infection of the myocardium or the effects of circulating toxins. Viral infections are the most common causes, such as Coxsackie (35 cases per 1000 infections) and influenza A and B (25 cases per 1000 infections) viruses. Myocarditis may occur several weeks after the initial viral symptoms, and susceptibility is increased by glucocorticoid treatment, immunosuppression, radiation, previous myocardial damage and exercise. Some bacterial and protozoal infections may be complicated by myocarditis; for example, approximately 5% of patients with Lyme disease (Borrelia burgdorferi, p. 255) develop myopericarditis, which is often associated with AV block. Toxins such as alcohol and drugs such as cocaine, lithium and doxorubicin may directly injure the myocardium. Other drugs, including penicillins and sulphonamides, and poisons such as lead and carbon monoxide may cause a hypersensitivity reaction and associated myocarditis. Occasionally, autoimmune conditions, such as systemic lupus erythematosus and rheumatoid arthritis, are associated with myocarditis.

Clinical features

Myocarditis may present in one of four ways:

- **Fulminant myocarditis** follows a viral prodrome or influenza-like illness and results in severe heart failure or cardiogenic shock.
- **Acute myocarditis** presents over a longer period with heart failure; it can lead to dilated cardiomyopathy.
- **Chronic active myocarditis** is rare and associated with chronic myocardial inflammation.
- **Chronic persistent myocarditis** is characterised by focal myocardial infiltrates and can cause chest pain and unnecessary causing ventricular dysfunction.

Myocarditis is self-limiting in most patients and the immediate prognosis is good. Death may, however, occur due to a ventricular arrhythmia or rapidly progressive heart failure. Myocarditis has been reported as a cause of sudden and unexpected death in young athletes. Some forms of myocarditis may lead to chronic low-grade myocarditis or dilated cardiomyopathy (see below). For example, in Chagas’ disease (p. 279), the patient frequently recovers from the acute infection but goes on to develop a chronic dilated cardiomyopathy 10 or 20 years later.

Investigations

The diagnosis of myocarditis is often made after other more common causes of cardiac dysfunction have been excluded. Echocardiography should be performed and may reveal left ventricular dysfunction that is sometimes regional (due to focal myocarditis). Cardiac MRI is also useful since it may show diagnostic patterns of myocardial inflammation or infiltration. The ECG is frequently abnormal but the changes are non-specific. Blood should be taken for analysis of troponin I and T, and creatine kinase. Levels may be elevated in the early phases. Occasionally, endomyocardial biopsy may be required to confirm the diagnosis.

Management

Treatment of myocarditis is primarily supportive. Treatment for cardiac failure or arrhythmias should be given and patients should be advised to avoid intense physical exertion because there is some evidence that this can induce potentially fatal ventricular arrhythmias. There is no evidence of benefit from treatment with glucocorticoids and immunosuppressive agents.

Specific antimicrobial therapy may be used if a causative organism has been identified but this is rare. Patients who do not respond adequately to medical treatment may temporarily require circulatory support with a mechanical ventricular assist device. Rarely, cardiac transplantation may be required.

Cardiomyopathy

Cardiomyopathies are primary diseases of the myocardium, which are classified according to their effects on cardiac structure and function (Fig. 16.99). They can be inherited or be caused by infections or exposure to toxins. In some cases no cause is identified.
Diseases of the myocardium

16

sporadic chest pain is a surprisingly frequent symptom. The differential diagnosis includes ventricular dysfunction due to CAD, and a diagnosis of dilated cardiomyopathy should be made only when this has been excluded.

Investigations

Echocardiography and cardiac MRI are the most useful investigations. Although ECG changes are common, they are non-specific. Genetic testing is indicated if more than one family member is diagnosed with the condition.

Management

The focus of management is to control heart failure using the strategies described earlier in this chapter (p. 464). Although some patients remain well for many years, the prognosis is variable and cardiac transplantation may be indicated. Patients with dilated cardiomyopathy and moderate or severe heart failure are at risk of sudden arrhythmic death and this can be reduced by rigorous medical therapy with β-blockers and either ACE inhibitors or ARBs. Some patients may be considered for implantation of a cardiac defibrillator and/or cardiac resynchronisation therapy (pp. 483 and 484).

Hypertrophic cardiomyopathy

This is the most common form of cardiomyopathy, with a prevalence of approximately 100 per 100,000. It is characterised by inappropriate and elaborate left ventricular hypertrophy with malalignment of the myocardial fibres and myocardial fibrosis. The hypertrophy may be generalised or confined largely to the interventricular septum (asymmetric septal hypertrophy, Fig. 16.99) or other regions of the heart. A specific variant termed apical hypertrophic cardiomyopathy is common in the Far East.

Pathogenesis
Hypertrophic cardiomyopathy is a genetic disorder, usually with autosomal dominant transmission, a high degree of penetrance and variable expression. In most patients, it is due to a single-point mutation in one of the genes that encode sarcomeric contractile proteins. There are three common groups of mutation with different phenotypes. Beta-myosin heavy-chain mutations are associated with hypertrophic hypertrophy. Troponin mutations are associated with little, and sometimes even no, hypertrophy but marked myocardial fibre disarray, exercise-induced hypotension and a high risk of sudden death. Myosin-binding protein C mutations tend to present late in life and are often associated with hypertension and arrhythmia. In all subtypes, heart failure may develop because the stiff, non-compliant LV impedes diastolic filling. Septal hypertrophy may also cause dynamic left ventricular outflow tract obstruction (hypertrophic obstructive cardiomyopathy, HOCM) and mitral regurgitation due to abnormal systolic anterior motion of the anterior mitral valve leaflet.

Clinical features
Effort-related symptoms, such as angina, breathlessness, arrhythmia and sudden death, are the dominant clinical presentations. The symptoms and signs are similar to those of aortic stenosis, except that, in hypertrophic cardiomyopathy, the character of the arterial pulse is jerky (Box 16.105). The annual mortality from sudden death is 2–3% among adults and 4–6% in children and adolescents (Box 16.106). Sudden death typically occurs during or just after vigorous physical activity and is thought to be due to ventricular arrhythmias. Hypertrophic cardiomyopathy is the most common cause of sudden death in young athletes. In patients who do not suffer fatal arrhythmias, the natural history is variable but clinical deterioration is often slow.

Investigations
Echocardiography is the investigation of choice and is usually diagnostic. Sometimes the diagnosis is more difficult when another cause of left ventricular hypertrophy is present but the degree of hypertrophy in hypertrophic cardiomyopathy is usually greater than in physiological hypertrophy and the pattern is asymmetrical. The ECG is abnormal and shows features of left ventricular hypertrophy with a wide variety of often bizarre abnormalities, including deep T-wave inversion. Genetic testing can be performed and is helpful in screening relatives of affected individuals.

Management
Beta-blockers, rate-limiting calcium antagonists and disopyramide can help to relieve symptoms and prevent syncopal attacks. Arrhythmias often respond to treatment with amiodarone. No pharmacological treatment has been identified that can improve prognosis, however. Outflow tract obstruction can be improved by partial surgical resection (myectomy) or by iatrogenic infarction of the basal septum (septal ablation) using a catheter-delivered alcohol solution. An ICD should be considered in patients with clinical risk factors for sudden death (Box 16.106). Digoxin and vasodilators may increase outflow tract obstruction and should be avoided.

Arrhythmogenic ventricular cardiomyopathy
Arrhythmogenic ventricular cardiomyopathy (AVC) predominantly affects the myocardium of the right ventricle. It is inherited in an autosomal dominant manner and has a prevalence of approximately 10 per 100,000. The genetic defect involves desmosomal protein genes, most commonly plakophilin 2 (PKP2), although current genetic testing protocols will not identify the culprit gene in many cases. It is characterised by replacement of patches of the right ventricular myocardium with fibrous and fatty tissue (see Fig. 16.99). In some cases, the LV is also involved and this is associated with a poorer prognosis. The diagnosis is based on a complex set of criteria that take account of the ECG, structural assessment, genetics and arrhythmias. The dominant clinical problems are ventricular arrhythmias, sudden death and right-sided cardiac failure. The ECG typically shows a slightly broadened QRS complex and inverted T waves in the right precordial leads. MRI is a helpful diagnostic tool and is used, along with the 12-lead ECG and ambulatory ECG monitoring, to screen the first-degree relatives of affected individuals. Management is based on treating right-sided cardiac failure with diuretics and cardiac arrhythmias with β-blockers or, in patients at high risk of sudden death, an implantable defibrillator can be offered.

Restrictive cardiomyopathy
In this rare condition, ventricular filling is impaired because the ventricles are ‘stiff’ (see Fig. 16.99). This leads to high atrial pressures with atrial hypertrophy, dilatation and, later, AF. Amyloidosis is the most common cause in the UK, although other forms of infiltration due to glycogen storage diseases, idiopathic perimyocyte fibrosis and a familial form of restrictive cardiomyopathy can also occur. The diagnosis can be difficult and requires assessment with Doppler echocardiography, CT or MRI, and endomyocardial biopsy. Treatment is symptomatic but the prognosis is usually poor and transplantation may be indicated.

---

**Box 16.105 Clinical features of hypertrophic cardiomyopathy**

**Symptoms**
- Angina on effort
- Dyspnoea on effort
- Syncope on effort
- Sudden death

**Signs**
- Jerky pulse*
- Palpable left ventricular hypertrophy
- Double impulse at the apex (palpable fourth heart sound due to left atrial hypertrophy)
- Mid-systolic murmur at the base*
- Parsystolic murmur (due to mitral regurgitation) at the apex

*Signs of left ventricular outflow tract obstruction may be augmented by standing up (reduced venous return), inotropes and vasodilators (e.g. sublingual nitrate).

**Box 16.106 Risk factors for sudden death in hypertrophic cardiomyopathy**

- A history of previous cardiac arrest or sustained ventricular tachycardia
- Recurrent syncope
- An adverse genotype and/or family history
- Exercise-induced hypotension
- Non-sustained ventricular tachycardia on ambulatory ECG monitoring
- Marked increase in left ventricular wall thickness
Obliterative cardiomyopathy

This is a rare form of restrictive cardiomyopathy, involving the endocardium of one or both ventricles; it is characterised by thrombosis and fibrosis, with gradual obliteration of the ventricular cavities by fibrous tissue (see Fig. 16.99). The mitral and tricuspid valves become regurgitant. Heart failure and pulmonary and systemic embolism are prominent features. It can sometimes be associated with eosinophilia and can occur in eosinophilic leukaemia and eosinophilic granulomatosis with polyangiitis (formerly known as Churg–Strauss syndrome, p. 1043). In tropical countries, the disease can be responsible for up to 10% of cardiac deaths. Mortality is high: 50% at 2 years. Anticoagulation and antiplatelet therapy are used, and diuretics may help symptoms of heart failure. Surgery (tricuspid and/or mitral valve replacement with decortication of the endocardium) may be helpful in selected cases.

Takotsubo cardiomyopathy

Takotsubo cardiomyopathy (Takotsubo syndrome) is a form of acute left ventricular dysfunction characterised by dilatation of the left ventricular apex and adjacent myocardium, with associated left ventricular impairment. The mechanism is poorly understood but may involve noradrenergic coronary vasoconstriction and acute left ventricular outflow obstruction. It is often associated with acute environmental or emotional stress (such as a bereavement) and presents with chest pain, breathlessness and sometimes cardiac failure. It occurs more frequently in women than in men. In terms of both symptoms and the ECG, the condition mimics acute ST elevation acute coronary syndrome. The diagnosis is usually made at coronary angiography, when CAD is found to be absent or minimal. Echocardiography then shows characteristic “apical ballooning” of the LV. The dilated apex and narrow outflow of the LV resemble a Japanese octopus trap, or takotsubo (Fig. 16.100).

Left ventricular dysfunction usually recovers within 4–5 days, although this can take weeks in some cases. Treatment is with a β-blocker, to prevent arrhythmia, and an ACE inhibitor, to treat left ventricular dysfunction. These drugs are continued only until cardiac function has recovered.

Secondary causes of cardiomyopathy

Many systemic conditions can produce a picture that is indistinguishable from dilated cardiomyopathy, including connective tissue disorders, sarcoidosis, haemochromatosis and alcoholic heart muscle disease (Box 16.107). In contrast, amyloidosis and eosinophilic heart disease produce symptoms and signs similar to those found in restrictive or obliteratorive cardiomyopathy, whereas the heart disease associated with Friedreich’s ataxia (p. 1116) can mimic hypertrophic cardiomyopathy.

Treatment and prognosis are determined by the underlying disorder. Abstention from alcohol may lead to a dramatic improvement in patients with alcoholic heart muscle disease.

Cardiac tumours

Primary cardiac tumours are rare (<0.2% of autopsies) but the heart and mediastinum may be the sites of metastases. Most primary tumours are benign (75%) and, of these, the majority are myxomas. The remainder are fibromas, lipomas, fibroelastomas and haemangiomas.

Atrial myxoma

Myxomas most commonly arise in the LA as single or multiple polypoid tumours, attached by a pedicle to the interatrial septum.
They are usually gelatinous but may be solid and even calcified, with superimposed thrombus.

On examination, the first heart sound is usually loud, and there may be a murmur of mitral regurgitation with a variable diastolic sound (tumour ‘plop’) due to prolapse of the mass through the mitral valve. The tumour can be detected incidentally on echocardiography, or following investigation of pyrexia, syncope, arrhythmias or emboli. Occasionally, the condition presents with malaise and features suggestive of a connective tissue disorder, including a raised ESR.

Treatment is by surgical excision. If the pedicle is removed, fewer than 5% of tumours recur.

**Diseases of the pericardium**

The normal pericardial sac contains about 50 mL of fluid, similar to lymph, which lubricates the surface of the heart. The pericardium limits distension of the heart, contributes to the haemodynamic interdependence of the ventricles, and acts as a barrier to infection. Nevertheless, congenital absence of the pericardium does not result in significant clinical or functional limitations.

### Acute pericarditis

This is due to an acute inflammatory process affecting the pericardium, which may coexist with myocarditis.

**Pathogenesis**

A number of causes are recognised (Box 16.108), but in some cases the cause is unclear. All forms of pericarditis may produce a pericardial effusion that, depending on the aetiology, may be fibrinous, serous, haemorrhagic or purulent. A fibrinous exudate may eventually lead to varying degrees of adhesion formation, whereas serous pericarditis often produces a large effusion of turbid, straw-coloured fluid with a high protein content. A haemorrhagic effusion is often due to malignant disease, particularly carcinoma of the breast or bronchus, and lymphoma. Purulent pericarditis is rare and may occur as a complication of sepsis, by direct spread from an intrathoracic infection, or from a penetrating injury.

**Clinical features**

The typical presentation is with chest pain that is retrosternal, radiates to the shoulders and neck, and is typically aggravated by deep breathing, movement, a change of position, exercise and swallowing. A low-grade fever is common. A pericardial friction rub is a high-pitched, superficial scratching or crunching noise, produced by movement of the inflamed pericardium, and is diagnostic of pericarditis; it is usually heard in systole but may also be audible in diastole and frequently has a ‘to-and-fro’ quality.

**Investigations**

The diagnosis can often be made on the basis of clinical features and the ECG; the latter shows ST elevation with upward concavity (Fig. 16.101) over the affected area, which may be widespread. PR interval depression is a very specific indicator of acute pericarditis. Later, there may be T-wave inversion, particularly if there is a degree of myocarditis. Echocardiography may be normal or may reveal pericardial effusion, in which case regular echocardiographic monitoring is recommended.

**Management**

The pain usually responds to aspirin (600 mg 6 times daily) but a more potent anti-inflammatory agent, such as indometacin (50 mg 3 times daily), may be required. Colchicine or glucocorticoids can also suppress symptoms but there is no evidence that they accelerate cure. In viral pericarditis, recovery usually occurs within a few days or weeks but there may be recurrences (chronic relapsing pericarditis). Purulent pericarditis requires treatment with antimicrobial therapy, pericardiocentesis and, if necessary, surgical drainage.

**16.108 Causes of acute pericarditis and pericardial effusion**

**Infection**

- Viral
- Bacterial
- Tuberculosis

**Inflammatory**

- Rheumatoid arthritis
- Systemic lupus erythematosus
- Rheumatic fever

**Other**

- Post-myocardial infarction
- Uraemia
- Malignancy
- Trauma

**Fig. 16.101 ECG in viral pericarditis.** Widespread ST elevation (leads I, II, aVL and V<sub>1</sub>–V<sub>6</sub>) is shown. The upward concave shape of the ST segments (see leads II and V<sub>6</sub>) and the unusual distribution of changes (involving anterior and inferior leads) help to distinguish pericarditis from acute myocardial infarction.
**Pericardial effusion**

Pericardial effusion often accompanies pericarditis and can have a number of causes, as shown in Box 16.108.

**Clinical features**

With the onset of an effusion the heart sounds may become quieter, and a friction rub, if present, may diminish in intensity but is not always abolished. Larger effusions may be accompanied by a sensation of retrosternal oppression. While most effusions do not have significant haemodynamic effects, large or rapidly developing effusions may cause cardiac tamponade. This term is used to describe acute heart failure due to compression of the heart and is described in detail below. Typical physical findings are a markedly raised JVP, hypotension, pulsus paradoxus (p. 448) and oliguria. Atypical presentations may occur when the effusion is localized as a result of previous pericarditis or cardiac surgery.

**Investigations**

Echocardiography is the definitive investigation and is helpful in monitoring the size of the effusion and its effect on cardiac function (Fig. 16.102). The QRS voltages on the ECG are often reduced in the presence of a large effusion. The QRS complexes may alternate in amplitude due to a to-and-fro motion of the heart within the fluid-filled pericardial sac (electrical alternans). The chest X-ray may show an increase in the size of the cardiac silhouette and, when there is a large effusion, this has a globular appearance. Aspiration of the effusion may be required for diagnostic purposes and, if necessary, for treatment of large effusions, as described below.

**Management**

Patients with large effusions that are causing haemodynamic compromise or cardiac tamponade should undergo aspiration of the effusion. This involves inserting a needle under echocardiographic guidance medial to the cardiac apex or below the xiphoid process, directed upwards towards the left shoulder. The route of choice will depend on the experience of the operator, the shape of the patient and the position of the effusion. A pericardial drain may be placed to provide symptomatic relief. Complications of pericardiocentesis include arrhythmias, damage to a coronary artery and bleeding, with exacerbation of tamponade as a result of injury to the RV. When tamponade is due to cardiac rupture or aortic dissection, pericardial aspiration may precipitate further potentially fatal bleeding and, in these situations, emergency surgery is the treatment of choice. A viscous, loculated or recurrent effusion may also require formal surgical drainage.

**Tuberculous pericarditis**

Tuberculous pericarditis may complicate pulmonary tuberculosis but may also be the first manifestation of the infection. In Africa, a tuberculous pericardial effusion is a common feature of AIDS (p. 322). The condition typically presents with chronic malaise, weight loss and a low-grade fever. An effusion usually develops and the pericardium may become thick and unyielding, leading to pericardial constriction or tamponade. An associated pleural effusion is often present.

The diagnosis may be confirmed by aspiration of the fluid and direct examination or culture for tubercle bacilli. Treatment requires specific antituberculous chemotherapy (p. 592); in addition, a 3-month course of prednisolone (initial dose 60 mg a day, tapering down rapidly) improves outcome.

**Chronic constrictive pericarditis**

Constrictive pericarditis is due to progressive thickening, fibrosis and calcification of the pericardium. In effect, the heart is encased in a solid shell and cannot fill properly. The calcification may extend into the myocardium, so there may also be impaired myocardial contraction. The condition often follows an attack of tuberculous pericarditis but can also complicate haemopericardium, viral pericarditis, rheumatoid arthritis and purulent pericarditis. It is often impossible to identify the original insult.

**Clinical features**

The symptoms and signs of systemic venous congestion are the hallmarks of constrictive pericarditis. AF is common and there is often dramatic ascites and hepatomegaly (Box 16.109). Breathlessness is not a prominent symptom because the lungs are seldom congested. The condition is sometimes overlooked but should be suspected in any patient with unexplained right heart failure and a small heart.

**Investigations**

A chest X-ray, which may show pericardial calcification (Fig. 16.103), and echocardiography often help to establish the diagnosis. CT scanning is useful for imaging the pericardial calcification. Constrictive pericarditis is often difficult to distinguish
aspiration of the fluid. The ECG may show features of the underlying disease, such as pericarditis or acute MI. When there is a large pericardial effusion, the ECG complexes are small and there may be electrical alternans: a changing axis with alternate beats caused by the heart swinging from side to side in the pericardial fluid. A chest X-ray shows an enlarged globular heart but can look normal.

Management
Cardiac tamponade is a medical emergency. When the diagnosis is confirmed, percutaneous pericardiocentesis should be performed as soon as possible, which usually results in a dramatic improvement. In some cases, surgical drainage may be required.

  - Stony dull R mid- and lower zones
- Auscultation
  - Absent breath sounds and vocal resonance R base
  - Bronchial breathing or crackles above effusion

Respiratory disease is responsible for a major burden of morbidity and untimely death, with conditions such as tuberculosis, pandemic influenza and pneumonia the most important in world health terms. The increasing prevalence of allergy, asthma and chronic obstructive pulmonary disease (COPD) contributes to the overall burden of chronic disease in the community. By 2025, the number of cigarette smokers worldwide is anticipated to increase to 1.5 billion, ensuring a growing burden of tobacco-related respiratory conditions.

Respiratory disease covers a breadth of pathologies, including infectious, inflammatory, neoplastic and degenerative processes. The practice of respiratory medicine thus requires collaboration with a range of disciplines. Recent advances have improved the lives of many patients with obstructive lung disease, cystic fibrosis, obstructive sleep apnoea and pulmonary hypertension, but the outlook remains poor for lung and other respiratory cancers and for some of the fibrosing lung conditions.

### Functional anatomy and physiology

The lungs occupy the upper two-thirds of the bony thorax, bounded medially by the spine, the heart and the mediastinum and inferiorly by the diaphragm. During breathing, free movement of the lung surface relative to the chest wall is facilitated by sliding contact between the parietal and visceral pleura, which cover the inner surface of the chest wall and the lung, respectively, and are normally in close apposition. Inspiration involves downward contraction of the dome-shaped diaphragm (innervated by the phrenic nerves originating from C3, 4 and 5) and upward, outward movement of the ribs on the costovertebral joints, caused by contraction of the external intercostal muscles (innervated by intercostal nerves originating from the thoracic spinal cord). Expiration is largely passive, driven by elastic recoil of the lungs.

The conducting airways from the nose to the alveoli connect the external environment with the extensive, thin and vulnerable alveolar surface. As air is inhaled through the upper airways, it is filtered in the nose, heated to body temperature and fully saturated with water vapour; partial recovery of this heat and moisture occurs on expiration. Total airway cross-section is smallest in the glottis and trachea, making the central airway particularly vulnerable to obstruction by foreign bodies and tumours. Normal breath sounds originate mainly from the rapid turbulent airflow in the larynx, trachea and main bronchi.

The multitude of small airways within the lung parenchyma has a very large combined cross-sectional area (over 300 cm² in the third-generation respiratory bronchioles), resulting in very slow flow rates. Airflow is virtually silent here and gas transport occurs largely by diffusion in the final generations. Major bronchial and pulmonary divisions are shown in Figure 17.1.

The acinus (Fig. 17.2) is the gas exchange unit of the lung and comprises branching respiratory bronchioles and clusters of alveoli. Here the air makes close contact with the blood in the pulmonary capillaries (gas-to-blood distance < 0.4 μm), and oxygen uptake and CO₂ excretion occur. The alveoli are lined with flattened epithelial cells (type I pneumocytes) and a few, more cuboidal, type II pneumocytes. The latter produce surfactant, which is a mixture of phospholipids that reduces surface tension and counteracts the tendency of alveoli to collapse under surface tension and pulmonary pressures.
tension. Type II pneumocytes can divide to reconstitute type I pneumocytes after lung injury.

**Lung mechanics**

Healthy alveolar walls contain a fine network of elastin and collagen fibres (Fig. 17.2). The volume of the lungs at the end of a tidal (‘normal’) breath out is called the functional residual capacity (FRC). At this volume, the inward elastic recoil of the lungs (resulting from elastin fibres and surface tension in the alveolar lining fluid) is balanced by the resistance of the chest wall to inward distortion from its resting shape, causing negative pressure in the pleural space. Elastin fibres allow the lung to be easily distended at physiological lung volumes, but collagen fibres cause increasing stiffness as full inflation is approached, so that, in health, the maximum inspiratory volume is limited by the lung (rather than the chest wall). Within the lung, the weight of tissue compresses the dependent regions and distends the uppermost parts, so a greater portion of an inhaled breath passes to the basal regions, which also receive the greatest blood flow as a result of gravity. Elastin fibres in alveolar walls maintain small airway patency by radial traction on the airway walls. Even in health, however, these small airways narrow during expiration because they are surrounded by alveoli at higher pressure, but are prevented from collapsing by radial elastic traction. The volume that can be exhaled is thus limited purely by the capacity of the expiratory muscles to distort the chest wall inwards. In emphysema, loss of alveolar walls leaves the small airways unsupported, and their collapse on expiration causes air trapping and limits expiration at a high end-expiratory volume (p. 575).

**Control of breathing**

The respiratory motor neurons in the posterior medulla oblongata are the origin of the respiratory cycle. Their activity is modulated by multiple external inputs in health and in disease (see Fig. 17.9):

- Central chemoreceptors in the ventrolateral medulla sense the pH of the cerebrospinal fluid (CSF) and are indirectly stimulated by a rise in arterial $P_{CO_2}$.
- The carotid bodies sense hypoxaemia but are mainly activated by arterial $P_{O_2}$ values below 8 kPa (60 mmHg). They are also sensitised to hypoxia by raised arterial $P_{CO_2}$.
- Muscle spindles in the respiratory muscles sense changes in mechanical load.
- Vagal sensory fibres in the lung may be stimulated by stretch, by inhaled toxins or by disease processes in the interstitium.
- Cortical (volitional) and limbic (emotional) influences can override the automatic control of breathing.

**Ventilation/perfusion matching and the pulmonary circulation**

To achieve optimal gas exchange within the lungs, the regional distribution of ventilation and perfusion must be matched. At
17.1 Respiratory function in old age

- **Reserve capacity**: a significant reduction in function can occur with ageing with only minimal effect on normal breathing, but the ability to combat acute disease is reduced.
- **Decline in FEV**: the FEV/FVC (forced expiratory volume/forced vital capacity, p. 55) ratio falls by around 0.2% per year from 70% at the age of 40–45 years, due to a decline in elastic recoil in the small airways with age. Smoking accelerates this decline threefold on average. Symptoms usually occur only when FEV, drops below 50% of predicted.
- **Increasing ventilation–perfusion mismatch**: the reduction in elastic recoil causes a tendency for the small airways to collapse during expiration, particularly in dependent areas of the lungs, thus reducing ventilation.
- **Reduced ventilatory responses to hypoxia and hypercapnia**: older people may be less tachypnoeic for any given fall in PaO₂ or rise in PaCO₂.
- **Impaired defences against infection**: due to reduced numbers of glandular epithelial cells, which lead to a reduction in protective mucus.
- **Decline in maximum oxygen uptake**: due to a combination of impairments in muscle, and the respiratory and cardiovascular systems. This leads to a reduction in cardiorespiratory reserve and exercise capacity.
- **Loss of chest wall compliance**: due to reduced intervertebral disc spaces and ossification of the costal cartilages; respiratory muscle strength and endurance also decline. These changes become important only in the presence of other respiratory disease.

segmental and subsegmental level, hypoxia constricts pulmonary arterioles and airway CO₂ dilates bronchi, helping to maintain good regional matching of ventilation and perfusion. Lung disease may create regions of relative under-ventilation or under-perfusion, which disturb this regional matching, causing respiratory failure (p. 565). In addition to causing ventilation–perfusion mismatch, diseases that destroy capillaries or thicken the alveolar capillary membrane (e.g. emphysema or fibrosis) can impair gas diffusion directly.

The pulmonary circulation in health operates at low pressure (approximately 24/9 mmHg) and can accommodate large increases in flow with minimal rise in pressure, e.g. during exercise. Pulmonary hypertension occurs when vessels are destroyed by emphysema, obstructed by thrombus, involved in interstitial inflammation or thickened by pulmonary vascular disease. The right ventricle responds by hypertrophy, with right axis deviation and P pulmonale (tall, peaked p waves) on the electrocardiogram (ECG), and clinical features of right heart failure; the term ‘cor pulmonale’ is often used for these findings.

**Lung defences**

**Upper airway defences**

Large airborne particles are trapped by nasal hairs, and smaller particles settling on the mucosa are cleared towards the oropharynx by the columnar ciliated epithelium that covers the turbinate and septum (Fig. 17.3). During cough, expiratory muscle effort against a closed glottis results in high intrathoracic pressure, which is then released explosively. The flexible posterior tracheal wall is pushed inwards by the high surrounding pressure, which reduces tracheal cross-section and thus maximises the airspeed to achieve effective expectoration. The larynx also acts as a sphincter, closing to protect the airway during swallowing and vomiting.

**Lower airway defences**

The sterility, structure and function of the lower airways are maintained by close cooperation between the innate and adaptive immune responses (pp. 62 and 67).

The innate response in the lungs is characterised by a number of non-specific defence mechanisms. Inhaled particulate matter is trapped in airway mucus and cleared by the mucociliary escalator. Cigarette smoke increases mucus secretion but reduces mucociliary clearance and predisposes towards lower respiratory tract infections, including pneumonia. Defective mucociliary transport is also a feature of several rare diseases, including Kartagener’s syndrome, Young’s syndrome and ciliary dysmotility syndrome, which are characterised by repeated sino-pulmonary infections and bronchiectasis.

Airway secretions contain an array of antimicrobial peptides (such as defensins, immunoglobulin A (IgA) and lysozyme), antiproteases and antioxidants. Many assist with the opsonisation and killing of bacteria and the regulation of the powerful proteolytic enzymes secreted by inflammatory cells. In particular, α1-antiprysin regulates neutrophil elastase, and deficiency of this may be associated with premature emphysema.

Macrophages engulf microbes, organic dusts and other particulate matter. They are unable to digest inorganic agents, such as asbestos or silica, which cause their death and lead to the release of powerful proteolytic enzymes that damage the lung. Neutrophil numbers in the airway are low but the pulmonary circulation contains a margination pool that may be recruited rapidly in response to bacterial infection. This may explain the prominence of lung injury in sepsis syndromes and trauma.

Adaptive immunity is characterised by the specificity of the response and the development of memory. Lung dendritic cells facilitate antigen presentation to T and B lymphocytes.

**Investigation of respiratory disease**

A detailed history, thorough examination and basic haematological and biochemical tests usually indicate the likely diagnosis and
differential. A number of other investigations are normally required to confirm the diagnosis and/or monitor disease activity.

**Imaging**

**The ‘plain’ chest X-ray**

This is performed on the majority of patients suspected of having chest disease. A posteroanterior (PA) film provides information on the lung fields, heart, mediastinum, vascular structures and thoracic cage (Fig. 17.4). Additional information may be obtained from a lateral film, particularly if pathology is suspected behind the heart shadow or deep in the diaphragmatic sulci. An approach to interpreting the chest X-ray is given in Box 17.2 and common abnormalities are listed in Box 17.3.

Increased shadowing may represent accumulation of fluid, lobar collapse or consolidation. Uncomplicated consolidation should not change the position of the mediastinum and the presence of an air bronchogram means that proximal bronchi are patent. Collapse (implying obstruction of the lobar bronchus) is accompanied by loss of volume and displacement of the mediastinum towards the affected side (Fig. 17.5).

The presence of ring shadows (thickened bronchi seen end-on), tramline shadows (thickened bronchi side-on) or tubular shadows (bronchi filled with secretions) suggests bronchiectasis, but computed tomography is a much more sensitive test than plain X-ray in bronchiectasis. The presence of pleural fluid is suggested by a dense basal shadow, which, in the erect patient, ascends towards the axilla (p. 547). In large pulmonary embolism, relative oligoemia may cause a lung field to appear abnormally dark.

**Fig. 17.4** The normal chest X-ray. The lung markings consist of branching and tapering lines radiating out from the hila. Where airways and vessels turn towards the film, they can appear as open or filled circles (see upper pole of right hilum). The scapulae may overlie the lung fields; trace the edge of bony structures to avoid mistaking them for pleural or pulmonary shadows. To check for hyperinflation, count the ribs; if more than 10 are visible posteriorly above the diaphragm, the lungs are hyperinflated. *From Innes JA. Davidson’s Essentials of medicine. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2009.*
Computed tomography (CT) provides detailed images of the pulmonary parenchyma, mediastinum, pleura and bony structures. The displayed range of densities can be adjusted to highlight different structures, such as the lung parenchyma, the mediastinal vascular structures or bone. Cross-sectional formatting allows recognition of the axial distribution of the disease, while coronal reformation displays the craniocaudal distribution. In cases of suspected lung cancer, CT is central to both diagnosis and staging, and facilitates percutaneous needle biopsy. CT identifies the extent and appearance of pleural thickening (Fig. 17.65) and reliably differentiates pleural and pericardial fat from other pathologies. High-resolution thin-section scanning provides detailed images of the pulmonary parenchyma and is particularly useful in assessing diffuse parenchymal lung disease (Fig. 17.56), identifying airway thickening, bronchiectasis (Fig. 17.29) and emphysema (Fig. 17.27). The relative contribution of competing pathologies to a breathless patient may be assessed. Prone imaging may be used to differentiate the gravity-induced posterobasal attenuation seen in supine scans. CT pulmonary angiography (CTPA) has become the investigation of choice in the diagnosis of pulmonary thromboembolism (Fig. 17.68), when it may either confirm the suspected embolism or highlight an alternative diagnosis. It has largely replaced the radioisotope-based ventilation–perfusion scan, although the latter continues to provide useful information in the pre-operative assessment of patients being considered for lung resection and in the assessment of pulmonary hypertension. CT may assist in identifying the cavitation of tuberculosis, fungal infection (p. 300) and other signs of infection (halo – air crescent). Finally, CT may be used to assess disease progression, thereby predicting prognosis, and in screening to detect the earliest signs of disease.
Investigation of respiratory disease

when paradoxical movement of the vocal cords may mimic asthma. Left-sided lung tumours may involve the left recurrent laryngeal nerve, paralysing the left vocal cord and leading to a hoarse voice and a ‘bovine’ cough. Continuous laryngoscopy during exercise tests allows the identification of exercise-induced laryngeal obstruction.

Bronchoscopy

The trachea and the first 3–4 generations of bronchi may be inspected using a flexible bronchoscope. Flexible bronchoscopy is usually performed under local anaesthesia with sedation, on an outpatient basis. Abnormal tissue in the bronchial lumen or wall can be biopsied, and bronchial brushings, washings or aspirates can be taken for cytological or bacteriological examination. Small biopsy specimens of lung tissue, taken by forceps passed through the bronchial wall (transbronchial biopsies), may be helpful in the diagnosis of bronchocentric disorders such as sarcoidosis and diffuse malignancy but are generally too small to be of diagnostic value in other diffuse parenchymal pulmonary disease (p. 605).

Rigid bronchoscopy requires general anaesthesia and is reserved for specific situations, such as massive haemoptysis or removal of foreignbody (see Fig. 10.2, p. 179), and can facilitate endobronchial laser therapy and stenting.

Endobronchial ultrasound

Endobronchial ultrasound (EBUS) allows directed needle aspiration from peribronchial nodes and is used increasingly to stage lung cancer. It may also be useful in the staging of mediastinal lymph nodes and distal metastatic disease in patients with lung cancer and in the investigation of pulmonary nodules. Co-registration of PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (Fig. 17.6). PET may also differentiate benign from malignant pleural disease and can be used to assess the extent of extrapulmonary disease in sarcoidosis. However, 18FDG uptake by a lesion is affected by a large number of parameters, including equipment used, the physics, and biological factors such as amount of body fat and brown fat uptake and the level of fasting blood glucose.

Magnetic resonance imaging

Conventional magnetic resonance imaging (MRI) of the lung parenchyma is seldom useful, although the technique is increasingly finding a role in the differentiation of benign from malignant pleural disease, and in delineating invasion of the chest wall or diaphragm by tumour.

Ultrasound

Transthoracic ultrasound has evolved into a point-of-care investigation to assess the pleural space (see Fig. 17.15). In the hands of an experienced operator it can distinguish pleural fluid from pleural thickening, identify a pneumothorax and, by directly visualising the diaphragm and solid organs such as the liver, spleen and kidneys, may be used to guide pleural aspiration, biopsy and intercostal chest drain insertion safely. It is also used to guide needle biopsy of superficial lymph node or chest wall masses and provides useful information on the shape and movement of the diaphragm.

Endoscopic examination

Laryngoscopy

The larynx may be inspected directly with a fibreoptic laryngoscope and this is useful in cases of suspected vocal cord dysfunction, when paradoxical movement of the vocal cords may mimic asthma. Left-sided lung tumours may involve the left recurrent laryngeal nerve, paralysing the left vocal cord and leading to a hoarse voice and a ‘bovine’ cough. Continuous laryngoscopy during exercise tests allows the identification of exercise-induced laryngeal obstruction.

Positron emission tomography

Positron emission tomography (PET) scanners employ the radiotracer 18F-fluorodeoxyglucose (FDG) to quantify the rate of glucose metabolism by cells. The 18FDG is rapidly taken up by metabolically active tissue, where it is phosphorylated and ‘trapped’ in the cell. The assessment of 18FDG uptake may be qualitative (visual analysis) or semi-quantitative, using the standardised uptake value (SUV) (Fig. 17.6). PET is useful in the staging of mediastinal lymph nodes and distal metastatic disease in patients with lung cancer and in the investigation of pulmonary nodules. Co-registration of PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (Fig. 17.6). PET may also differentiate benign from malignant pleural disease and can be used to assess the extent of extrapulmonary disease in sarcoidosis. However, 18FDG uptake by a lesion is affected by a large number of parameters, including equipment used, the physics, and biological factors such as amount of body fat and brown fat uptake and the level of fasting blood glucose.

Magnetic resonance imaging

Conventional magnetic resonance imaging (MRI) of the lung parenchyma is seldom useful, although the technique is increasingly finding a role in the differentiation of benign from malignant pleural disease, and in delineating invasion of the chest wall or diaphragm by tumour.

Ultrasound

Transthoracic ultrasound has evolved into a point-of-care investigation to assess the pleural space (see Fig. 17.15). In the hands of an experienced operator it can distinguish pleural fluid from pleural thickening, identify a pneumothorax and, by directly visualising the diaphragm and solid organs such as the liver, spleen and kidneys, may be used to guide pleural aspiration, biopsy and intercostal chest drain insertion safely. It is also used to guide needle biopsy of superficial lymph node or chest wall masses and provides useful information on the shape and movement of the diaphragm.

Endoscopic examination

Laryngoscopy

The larynx may be inspected directly with a fibreoptic laryngoscope and this is useful in cases of suspected vocal cord dysfunction, when paradoxical movement of the vocal cords may mimic asthma. Left-sided lung tumours may involve the left recurrent laryngeal nerve, paralysing the left vocal cord and leading to a hoarse voice and a ‘bovine’ cough. Continuous laryngoscopy during exercise tests allows the identification of exercise-induced laryngeal obstruction.

Positron emission tomography

Positron emission tomography (PET) scanners employ the radiotracer 18F-fluorodeoxyglucose (FDG) to quantify the rate of glucose metabolism by cells. The 18FDG is rapidly taken up by metabolically active tissue, where it is phosphorylated and ‘trapped’ in the cell. The assessment of 18FDG uptake may be qualitative (visual analysis) or semi-quantitative, using the standardised uptake value (SUV) (Fig. 17.6). PET is useful in the staging of mediastinal lymph nodes and distal metastatic disease in patients with lung cancer and in the investigation of pulmonary nodules. Co-registration of PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (Fig. 17.6). PET may also differentiate benign from malignant pleural disease and can be used to assess the extent of extrapulmonary disease in sarcoidosis. However, 18FDG uptake by a lesion is affected by a large number of parameters, including equipment used, the physics, and biological factors such as amount of body fat and brown fat uptake and the level of fasting blood glucose.

Magnetic resonance imaging

Conventional magnetic resonance imaging (MRI) of the lung parenchyma is seldom useful, although the technique is increasingly finding a role in the differentiation of benign from malignant pleural disease, and in delineating invasion of the chest wall or diaphragm by tumour.

Ultrasound

Transthoracic ultrasound has evolved into a point-of-care investigation to assess the pleural space (see Fig. 17.15). In the hands of an experienced operator it can distinguish pleural fluid from pleural thickening, identify a pneumothorax and, by directly visualising the diaphragm and solid organs such as the liver, spleen and kidneys, may be used to guide pleural aspiration, biopsy and intercostal chest drain insertion safely. It is also used to guide needle biopsy of superficial lymph node or chest wall masses and provides useful information on the shape and movement of the diaphragm.
Immunological and serological tests

The diagnosis of asthma may be supported by demonstrating an elevated level of immunoglobulin E (IgE), and the measurement of IgE directed against specific antigens can be useful in assessing the contribution of specific allergens to the presentation. Many autoimmune diseases present with pulmonary involvement and autoantibodies may be identified in the serum. Serum precipitins are antibodies that form visible lines of precipitated glycoprotein when they encounter their specific antigen in an agarose gel or on an acetate cellulose sheet. They may identify a reaction to fungi such as Aspergillus (p. 596) or to antigens involved in hypersensitivity pneumonitis, such as farmer’s lung (p. 616). IgG enzyme immunoassay may be used interchangeably. The presence of pneumococcal antigen in sputum, blood or urine may be of diagnostic importance in pneumonia. Respiratory viruses can be detected in nose/throat swabs by immunofluorescence and Legionella infection may be diagnosed by detection of the urinary antigen. The detection of galactomannan, a component of the cell wall of Aspergillus, may assist in the diagnosis of invasive aspergillosis, and interferon-gamma release assays are useful in the detection of latent tuberculosis.

Microbiological investigations

Sputum, pleural fluid, throat swabs, blood, and bronchial washings and aspirates can be examined for bacteria, fungi and viruses. The use of hypertonic saline to induce expectoration of sputum may obviate the need for more invasive procedures, such as bronchoscopy. Molecular tests are increasingly being used to provide rapid and accurate identification of many infective organisms. Nucleic acid amplification tests (NAATs) identify common respiratory viruses, such as influenza, adenovirus and respiratory syncytial virus, and have largely replaced paired serology for Mycoplasma, Legionella and other organisms. NAATs are increasingly adopted as the first-line investigation for identification of tuberculosis and rapid identification of drug resistance.

Cytology and histopathology

Cytological examination of exfoliated cells in pleural fluid or bronchial brushings and washings, or of fine needle aspirates from lymph nodes or pulmonary lesions, can support a diagnosis of malignancy but a larger tissue biopsy is often necessary, particularly as this allows immunohistochemistry using a panel of antibodies to characterise the tumour. Histopathology may also allow identification of infective agents such as Mycobacterium tuberculosis, Pneumocystis jirovecii or fungi. Differential cell counts in bronchial lavage fluid may help to distinguish pulmonary changes due to sarcoidosis (p. 608) from those caused by idiopathic pulmonary fibrosis (p. 605) or hypersensitivity pneumonitis (p. 616).

Respiratory function testing

Respiratory function tests are used to aid diagnosis, quantify functional impairment, and monitor treatment or progression of disease. Airway narrowing, lung volume and gas exchange capacity are quantified and compared with normal values.

Fig. 17.7 Respiratory function tests in health and disease. A Volume/time traces from forced expiration in health, chronic obstructive pulmonary disease (COPD) and fibrosis. COPD causes slow, prolonged and limited exhalation. In fibrosis, forced expiration results in rapid expiratory of a reduced forced vital capacity (FVC). Forced expiratory volume (FEV₁) is reduced in both diseases but disproportionately so, compared to FVC, in COPD. B The same data plotted as flow/volume loops. In COPD, collapse of intrathoracic airways limits flow, particularly during mid- and late expiration. The blue trace illustrates large airway obstruction, which particularly limits peak flow rates. C Lung volume measurement. Volume/time graphs during quiet breathing with a single maximal breath in and out. COPD causes hyperinflation with increased residual volume. Fibrosis causes a proportional reduction in all lung volumes.
adjusted for age, gender, height and ethnic origin. In diseases characterised by airway narrowing (e.g. asthma, bronchitis and emphysema), maximum expiratory flow is limited by dynamic compression of small intrathoracic airways, some of which may close completely during expiration, limiting the volume which can be expired (‘obstructive’ defect). Hyperinflation of the chest results and can become extreme if elastic recoil is also lost due to parenchymal destruction, as in emphysema. In contrast, diseases that cause interstitial inflammation and/or fibrosis lead to progressive loss of lung volume (‘restrictive’ defect) with normal expiratory flow rates. Typical laboratory traces are illustrated in Figure 17.7.

### Measurement of airway obstruction

Airway narrowing is assessed by asking patients to breathe in fully, then blow out as hard and fast as they can into a peak flow meter or a spirometer. Peak flow meters are cheap and convenient for home monitoring of peak expiratory flow (PEF) in the detection and monitoring of asthma but results are effort-dependent. More accurate and reproducible measures are obtained by maximum forced expiration into a spirometer. The forced expired volume in 1 second (FEV₁) is the volume exhaled in the first second, and the forced vital capacity (FVC) is the total volume exhaled. FEV₁ is disproportionately reduced in airflow obstruction, resulting in FEV₁/FVC ratios of less than 70%. In this situation, spirometry should be repeated following inhaled short-acting β₂-agonist bronchodilators (e.g. salbutamol); an increase of >12% and >200 mL in FEV₁ or FVC indicates significant reversibility. A large improvement in FEV₁ (>400 mL) and variability in peak flow over time are features of asthma (p. 567).

To distinguish large airway narrowing (e.g. tracheal stenosis or compression; see Fig. 18.12, p. 648) from small airway narrowing, spirometry data are plotted as flow/volume loops. These display flow in relation to lung volume (rather than time) during maximum expiration and inspiration, and the pattern of flow reveals the site of airflow obstruction (Fig. 17.7B).

### Lung volumes

Spirometry can measure only the volume of gas that can be exhaled; it cannot measure the gas remaining in the lungs after a maximal expiration. All the gas in the lungs can be measured by rebreathing an inert non-absorbed gas (usually helium) and recording how much the test gas is diluted by lung gas at equilibrium. This measures the volume of intrathoracic gas that mixes freely with tidal breaths. Alternatively, lung volume may be measured by body plethysmography (p. 175), which determines the pressure/volume relationship of the thorax. This method measures total intrathoracic gas volume, including poorly ventilated areas such as bullae. The terms used to describe lung volume are shown in Figure 17.7C.

### Transfer factor

To measure the capacity of the lungs to exchange gas, patients inhale a test mixture of 0.3% carbon monoxide, which is taken up avidly by haemoglobin in pulmonary capillaries. After a short breath-hold, the rate of disappearance of CO into the circulation is calculated from a sample of expire, and expressed as the TLCO or carbon monoxide transfer factor. Helium is also included in the test breath to allow calculation of the volume of lung examined by the test breath. Transfer factor expressed per unit lung volume is termed KCO. Common respiratory function abnormalities are summarised in Box 17.4.

**Fig. 17.8 Changes in blood [H⁺], PaCO₂ and plasma [HCO₃⁻] in acid–base disorders.** The rectangle indicates normal limits for [H⁺] and PaCO₂. The bands represent 95% confidence limits of single disturbances in human blood. To determine the likely cause of an acid–base disorder, plot the values of [H⁺] and PaCO₂ from an arterial blood gas measurement. The diagram indicates whether any acidosis or alkalosis results primarily from a respiratory disorder of PaCO₂ or from a metabolic derangement. Reprinted with permission from Elsevier (Flanery D. Lancer 1971; 1:1921).

**Arterial blood gases and oximetry**

The measurement of hydrogen ion concentration, PaO₂ and PaCO₂, and derived bicarbonate concentration in an arterial blood sample is essential for assessing the degree and type of respiratory failure and for measuring acid–base status. This is discussed in detail on pages 363 and 565. Interpretation of results is made easier by blood gas diagrams (Fig. 17.8), which indicate whether any acidosis or alkalosis is due to acute or chronic respiratory derangements of PaCO₂, or to metabolic causes.

Pulse oximeters with finger or ear probes measure the difference in absorbance of light by oxygenated and deoxygenated blood and calculate the percentage of haemoglobin that is oxygenated (the oxygen saturation). This allows non-invasive continuous
assessment of oxygen saturation in patients and its response to oxygen therapy.

### Exercise tests

Resting measurements may be unhelpful in early disease or in patients complaining only of exercise-induced symptoms. Exercise testing with spirometry before and after can help to reveal exercise-induced asthma. Walk tests include the self-paced 6-minute walk and the externally paced incremental ‘shuttle’ test, where patients walk at increasing pace between two cones 10 m apart. These provide simple, repeatable assessments of disability and response to treatment. Cardiopulmonary bicycle exercise testing, with measurement of metabolic gas exchange, ventilation and ECG changes, is useful for quantifying exercise limitation and detecting occult cardiovascular or respiratory limitation in a breathless patient.

### Presenting problems in respiratory disease

#### Cough

Cough is the most frequent symptom of respiratory disease and is caused by stimulation of sensory nerves in the mucosa of the pharynx, larynx, trachea and bronchi. Acute sensitisation of the normal cough reflex occurs in a number of conditions and it is typically induced by changes in air temperature or exposure to irritants, such as cigarette smoke or perfumes. Distinguishing characteristics of various causes of cough are detailed in Box 17.5.

The explosive quality of a normal cough is lost in patients with respiratory muscle paralysis or vocal cord palsy. Paralysis of a single vocal cord gives rise to a prolonged, low-pitched, inefficient ‘bovine’ cough accompanied by hoarseness. Coexistence of an inspiratory noise (stridor) indicates partial obstruction of a major airway (e.g. laryngeal oedema, tracheal tumour, scarring, compression or inhaled foreign body) and requires urgent investigation and treatment. Sputum production is common in patients with acute or chronic cough, and its nature and appearance can provide clues to the aetiology (p. 546).

### Aetiology

Acute transient cough is most commonly caused by viral lower respiratory tract infection, post-nasal drip resulting from rhinitis or sinusitis, aspiration of a foreign body, or throat-clearing secondary to laryngitis or pharyngitis. When cough occurs in the context of more serious diseases, such as pneumonia, aspiration, congestive heart failure or pulmonary embolism, it is usually easy to diagnose from other clinical features.

Patients with chronic cough present more of a challenge, especially when physical examination, chest X-ray and lung function studies are normal. In this context, it is most often explained by cough-variant asthma (where cough may be the principal or exclusive clinical manifestation), post-nasal drip secondary to nasal or sinus disease, or gastro-oesophageal reflux disease (GORD) with aspiration. Diagnosis of the latter may require oesophageal pH monitoring or a prolonged trial of anti-reflux therapy (p. 793). Between 10% and 15% of patients (particularly women) taking angiotensin-converting enzyme (ACE) inhibitors develop a drug-induced chronic cough. Bordetella pertussis infection in adults (p. 582) can result in cough lasting up to 3 months. While most patients with lung cancer have an abnormal chest X-ray on presentation, fibreoptic bronchoscopy or thoracic CT is advisable in most adults (especially smokers) with otherwise unexplained cough of recent onset, as this may reveal a small endobronchial tumour or unexpected foreign body (see Fig. 10.2, p. 179). In a small percentage of patients, dry cough may be the presenting feature of interstitial lung disease.

Adapted from Munro JF, Campbell IW. Macleod’s Clinical examination, 10th edn. Edinburgh: Churchill Livingstone, Elsevier Ltd; 2000.
Breathlessness or dyspnoea can be defined as the feeling of an uncomfortable need to breathe. It is unusual among sensations, as it has no defined receptors, no localised representation in the brain, and multiple causes both in health (e.g. exercise) and in diseases of the lungs, heart or muscles.

Pathophysiology
Stimuli to breathing resulting from disease processes are shown in Figure 17.9. Respiratory diseases can stimulate breathing and dyspnoea by:
- stimulating intrapulmonary sensory nerves (e.g. pneumothorax, interstitial inflammation and pulmonary embolus)
- increasing the mechanical load on the respiratory muscles (e.g. airflow obstruction or pulmonary fibrosis)
- causing hypoxia, hypercapnia or acidosis, which stimulate chemoreceptors.

In cardiac failure, pulmonary congestion reduces lung compliance and can also obstruct the small airways. Reduced cardiac output also limits oxygen supply to the skeletal muscles during exercise, causing early lactic acidemia and further stimulating breathing via the central chemoreceptors.

Breathlessness and the effects of treatment can be quantified using a symptom scale. Patients tend to report breathlessness in proportion to the sum of the above stimuli to breathing.

Fig. 17.9 Respiratory stimuli contributing to breathlessness. Mechanisms by which disease can stimulate the respiratory motor neurons in the medulla. Breathlessness is usually felt in proportion to the sum of these stimuli. Further explanation is given on page 179. (CSF = cerebrospinal fluid; V/Q = ventilation/perfusion match)
How much can you do on a good day?

Noting ‘breathless on exertion’ is not enough; the approximate distance the patient can walk on the level should be documented, along with capacity to climb inclines or stairs. Variability within and between days is a hallmark of asthma; in mild asthma, the patient may be free of symptoms and signs when well. Gradual, progressive loss of exercise capacity over months and years, with consistent disability over days, is typical of COPD. When asthma is suspected, the degree of variability is best documented by home peak flow monitoring.

Relentless, progressive breathlessness that is also present at rest, often accompanied by a dry cough, suggests interstitial fibrosis. Impaired left ventricular function can also cause chronic exertional breathlessness, cough and wheeze. A history of angina, hypertension or myocardial infarction raises the possibility of a cardiac cause. This may be confirmed by a displaced apex beat, a raised JVP and cardiac murmurs (although these signs can occur in patients with musculoskeletal disease impairing respiratory function (e.g. kyphoscoliosis or muscular dystrophy).

Did you have breathing problems in childhood or at school?

When present, a history of childhood wheeze increases the likelihood of asthma, although this history may be absent in late-onset asthma. A history of atopic allergy also increases the likelihood of asthma.

Do you have other symptoms along with your breathlessness?

Digital or perioral paraesthesiae and a feeling that ‘I cannot get a deep enough breath in’ are typical features of psychogenic hyperventilation but this cannot be diagnosed until investigations have excluded other potential causes. Additional symptoms include lightheadedness, central chest discomfort or even carpopedal spasm due to acute respiratory alkalosis. These alarming symptoms may provoke further anxiety and exacerbate hyperventilation. Psychogenic breathlessness rarely disturbs sleep, frequently occurs at rest, may be provoked by stressful situations and may even be relieved by exercise. The Nijmegen questionnaire can be used to score some of the typical symptoms of hyperventilation (Box 17.7). Arterial blood gases show normal $P_{\text{a}}O_2$, low $P_{\text{a}}CO_2$ and alkalosis.

Pleuritic chest pain in a patient with chronic breathlessness, particularly if it occurs in more than one site over time, should raise suspicion of thromboembolic disease. Thromboembolism may occasionally present as chronic breathlessness with no other specific features and should always be considered before a diagnosis of psychogenic hyperventilation is made.

Morning headache is an important symptom in patients with breathlessness, as it may signal the onset of carbon dioxide retention and respiratory failure. This is particularly significant in patients with musculoskeletal disease impairing respiratory function (e.g. kyphoscoliosis or muscular dystrophy).

### Acute severe breathlessness

This is one of the most common and dramatic medical emergencies. Although respiratory causes are common, it can result from cardiac disease, metabolic disease or poisoning causing acidosis, or from psychogenic causes. The approach to patients with acute severe breathlessness is covered on page 179.

#### Chest pain

Chest pain can result from cardiac, respiratory, oesophageal or musculoskeletal disorders. The approach to this common symptom is covered on page 176.
Finger clubbing describes painless swelling of the soft tissues of the terminal phalanges, causing increased longitudinal and lateral convexity of the nail (Fig. 17.10). Upward displacement of the proximal nail margin causes the anteroposterior diameter of the finger at that point to exceed that at the distal interphalangeal joint. It also removes the normal hyponychial angle between the proximal part of the nail and the adjoining skin. Clubbing usually affects the fingers symmetrically and commonly also involves the toes, but can be unilateral if caused by a proximal vascular condition, e.g. arteriovenous shunts for dialysis. It is sometimes congenital but in over 90% of patients it indicates a serious underlying disorder. The most common underlying causes are suppurative or malignant lung disease but a variety of other conditions can cause clubbing (Box 17.8). Clubbing may recede if the underlying condition resolves, e.g. following lung transplantation for cystic fibrosis.

Haemoptysis

Coughing up blood, irrespective of the amount, is an alarming symptom and patients nearly always seek medical advice. Care should be taken to establish that it is true haemoptysis and not haematemesis, or gum or nose bleeding. Haemoptysis must always be assumed to have a serious cause until this is excluded (Box 17.9).

Many episodes of haemoptysis remain unexplained, even after full investigation, and are likely to be due to simple bronchial infection. A history of repeated small haemoptysis, or blood-streaking of sputum, is highly suggestive of lung cancer. Fever, night sweats and weight loss suggest tuberculosis. Pneumococcal pneumonia often causes ‘rusty’-coloured sputum but can cause frank haemoptysis, as can all suppurative pneumonic infections, including lung abscess (p. 586). Bronchiectasis (p. 578) and intracavitary mycetoma (p. 597) can cause catastrophic bronchial haemorrhage, and in these patients there may be a history of previous tuberculosis or pneumonia in early life. Finally, pulmonary thromboembolism is a common cause of haemoptysis and should always be considered.

Physical examination may reveal additional clues. Finger clubbing suggests lung cancer or bronchiectasis; other signs of malignancy, such as cachexia, hepatomegaly and lymphadenopathy, should also be sought. Fever, pleural rub and signs of consolidation occur in pneumonia or pulmonary infarction; a minority of patients with pulmonary infarction also have unilateral leg swelling or pain suggestive of deep venous

The ‘incidental’ pulmonary nodule

A pulmonary nodule may be defined as a well or poorly circumscribed, approximately rounded structure that appears on imaging as a focal opacity less than 3 cm in diameter that is surrounded by aerated lung. The increased use of helical multi-detector CT (Fig 17.12) has been accompanied by an epidemic of ‘incidental’ pulmonary nodules. Nodules must not be dismissed as ‘incidental’, however, until an important and treatable infective or malignant condition in its earliest stage is excluded or stability over at least 2 years has been demonstrated.

The list of potential causes of pulmonary nodules is extensive and most are benign (Box 17.10). Features on a CT scan consistent with a benign lesion include being less than 5 mm in diameter or less than 80 mm³ in volume; diffuse, central, laminated or popcorn calcification; or the presence of macroscopic fat. In addition, perifissural lymph nodes and subpleural nodules with a lentiform or triangular shape do not require any further investigation.

In cases where a benign lesion cannot be confidently assumed, further assessment depends on both the appearance of the nodule and the clinical context. These assessments may be aided by the use of computer prediction models (Box 17.11).

Management

In severe acute haemoptysis, the patient should be nursed upright (or on the side of the bleeding, if this is known), given high-flow oxygen and resuscitated as required. Bronchoscopy in the acute phase is difficult and often merely shows blood throughout the bronchial tree. Infusions of the antifibrinolytic agent tranexamic acid or the vasopressin precursor terlipressin may help to limit bleeding but evidence of efficacy is limited. If radiology shows an obvious central cause, then rigid bronchoscopy under general anaesthesia may allow intervention to stop bleeding; however, the source often cannot be visualised. Intubation with a divided endotracheal tube may allow protected ventilation of the unaffected lung to stabilise the patient. Bronchial arteriography and embolisation (Fig. 17.11), or even emergency surgery, can be life-saving in the acute situation.

In the vast majority of cases, however, the haemoptysis itself is not life-threatening and a logical sequence of investigations can be followed:

- chest X-ray, which may provide evidence of a localised lesion, including tumour (malignant or benign), pneumonia, mycetoma or tuberculosis
- full blood count (FBC) and clotting screen
- bronchoscopy after acute bleeding has settled, which may reveal a central lung cancer (not visible on the chest X-ray) and permit biopsy and tissue diagnosis
- CTPA, which may show underlying pulmonary thromboembolic disease or alternative causes not seen on the chest X-ray (e.g. pulmonary arteriovenous malformation or small or hidden tumours).

thrombosis. Rashes, haematuria and digital infarcts point to an underlying systemic disease, such as a vasculitis, which may be associated with haemoptysis.

Common causes

- Lung cancer
- Single metastasis
- Localised pneumonia
- Lung abscess
- Tuberculosis
- Pulmonary infarct

Uncommon causes

- Benign tumour
- Lymphoma
- Arteriovenous malformation
- Hydatid cyst (p. 298)
- Bronchogenic cyst
- Rheumatoid nodule
- Granulomatosis with polyangiitis (Wegener’s granulomatosis)
- Pulmonary sequestration
- Pulmonary haematoma
- ‘Pseudotumour’ – fluid collection in a fissure
- Aspergiloma (usually surrounded by air crescent)
- Cryptococcus
- Aspergillus nodule

*Linear or sheet-like lung opacities are unlikely to represent neoplasms and do not require follow-up. Some nodular opacities may be sufficiently typical of scarring for follow-up not to be warranted.

---

**Fig. 17.13 Recommendations on the assessment of a solid pulmonary nodule.**

A initial approach to solid pulmonary nodules. The Brock model is an online calculator that can also be downloaded as an app (https://brocku.ca/lung-cancer-risk-calculator). The model integrates data on age, sex, family history of cancer, the presence of emphysema, nodule size, nodule type, nodule position, nodule count and speculation, and calculates the probability that a nodule will become malignant within a 2- to 4-year follow-up period. Herder is a similar model. *Consider positron emission tomography–computed tomography (PET-CT) for larger nodules in young patients with low risk by Brock score, as this score was developed in a screening cohort (50–75 years) and so performance in younger patients is unproven. Continues overleaf.
Baseline volumetric analysis (or diameter measurement if volumetry not available/technically impossible)

- ≥80mm³ volume or ≥6mm diameter
- CT 3 months after baseline
- CT 1 year after baseline
- VDT ≤400 days or clear evidence of growth?

- Stable on basis of 2D non-automated diameter value
- Stable on basis of volumetry
- VDT >600 days
- VDT 400–600 days
- VDT ≤400 days or clear evidence of growth

- CT 2 years after baseline
- Discharge
- Consider discharge (only if based on volumetry) or ongoing surveillance depending on patient preference
- Consider biopsy or further CT surveillance depending on patient preference
- Further workup and consideration of definitive management

A variety of diagnostic approaches may be considered, including bronchoscopy, percutaneous needle biopsy, PET, interval CT scanning or even surgical resection of the lesion. Pulmonary nodules are invariably beyond the vision of the bronchoscope and, with the notable exception of pulmonary infection (e.g. tuberculosis), the yield from blind washings is low, although this may improve as advances in endobronchial imaging are adopted. If the nodule is favourably located and of sufficient size, percutaneous needle biopsy under ultrasound or CT guidance may be employed. The risk of pneumothorax is approximately 15% and around 7% require intercostal drainage, so this should be contemplated only in individuals with an FEV₁ of more than 35% predicted. Haemorrhage into the lung or pleural space, air embolism and tumour seeding are rare but recognised complications.

Where clinical suspicion remains high despite a benign or indeterminate biopsy or where a nodule is considered to be of sufficiently high risk for malignancy to merit proceeding straight to surgery, then surgical resection may be the best management, as surgery remains the best chance of curing lung cancer. It is important for the logic underlying this approach to be discussed with the patient and the consequences of resection of a benign lesion explained.

PET scanning provides useful information about nodules of at least 1 cm in diameter. The presence of high metabolic activity is strongly suggestive of malignancy, while an inactive ‘cold’ nodule is consistent with benign disease. However, a high SUV is a marker of glucose metabolism, not malignancy, and PET has significant limitations in regions with high endemic rates of infectious or granulomatous disease. False-negative results may occur with neuro-endocrine tumours and minimally invasive lepidic adenocarcinoma. Detection of neuro-endocrine tumours may be improved by the use of 68Ga-Dotatoc in place of FDG.

If the nodule is small and inaccessible, interval CT scanning may be employed. A repeat CT scan at 3 months will reliably detect growth in larger nodules and may also demonstrate resolution. Further interval scans may be arranged, depending on the clinical context (Fig. 17.13).

Particular care must be taken with subsolid nodules, particularly if further imaging demonstrates the development of a new solid component, as these may represent a pre-malignant or an early invasive form of adenocarcinoma.

In cases where the probability of cancer is low, the potential risk of further scanning must be considered. Subsequent scans often detect further nodules, increase the risk of false-positive findings and lead to unnecessary patient anxiety while exposing the individual to increased radiation.

**Pleural effusion**

The accumulation of serous fluid within the pleural space is termed pleural effusion. The accumulation of frank pus is termed empyema (p. 564), that of blood is haemothorax, and that of chyle is a chylothorax. In general, pleural fluid accumulates as a result of either increased hydrostatic pressure or decreased osmotic pressure (‘transudative’ effusion, as seen in cardiac, liver or renal failure), or from increased microvascular pressure due to disease of the pleura or injury in the adjacent lung (‘exudative’
Presenting problems in respiratory disease

Clinical assessment
Symptoms (pain on inspiration and coughing) and signs of pleurisy (a pleural rub) often precede the development of an effusion, especially in patients with underlying pneumonia, pulmonary infarction or connective tissue disease. When breathlessness is the only symptom, however, the onset may be insidious, depending on the size and rate of accumulation. The physical signs are detailed on page 547.

Investigations

Radiological investigations
The classical appearance of pleural fluid on the erect PA chest film is of a curved shadow at the lung base, blunting the costophrenic angle and ascending towards the axilla (p. 547). Fluid appears to track up the lateral chest wall. In fact, fluid surrounds the whole lung at this level but casts a radiological shadow only where the X-ray beam passes tangentially across the fluid against the lateral chest wall. Around 200 mL of fluid is required in order for it to be detectable on a PA chest X-ray. Previous scarring or adhesions in the pleural space can cause localised effusions. Pleural fluid localised below the lower lobe (“subpulmonary effusion”) simulates an elevated hemidiaphragm. Pleural fluid localised within an oblique fissure may produce a rounded opacity that may be mistaken for a tumour.

Ultrasound is more accurate than plain chest X-ray for determining the presence of fluid. A clear hypoechoic space is consistent with a transudate and the presence of moving, floating densities suggests an exudate. The presence of septation most likely indicates an evolving empyema or resolving haemothorax. CT scanning is indicated where malignant disease is suspected.

Pleural aspiration and biopsy
In some conditions (e.g. left ventricular failure), it should not be necessary to sample fluid unless atypical features are present; appropriate treatment should be administered and the effusion re-evaluated. In most other circumstances, however, diagnostic sampling is required. Simple aspiration provides information on the colour and texture of fluid and these alone may immediately suggest an empyema or chylothorax. The presence of blood is consistent with pulmonary infarction or malignancy but may result from a traumatic tap. Biochemical analysis allows classification into

*May cause bilateral effusions.
transudate and exudate (Box 17.14) and Gram stain may suggest parapneumonic effusion. The predominant cell type provides useful information and cytological examination is essential. A low pH suggests infection but may also be seen in rheumatoid arthritis, ruptured oesophagus or advanced malignancy.

Ultrasound- or CT-guided pleural biopsy provides tissue for pathological and microbiological analysis. Where necessary, video-assisted thoracoscopy allows visualisation of the pleura and direct guidance of a biopsy.

**Management**

Therapeutic aspiration may be required to palliate breathlessness but removing more than 1.5 L at a time is associated with a small risk of re-expansion pulmonary oedema. An effusion should never be drained to dryness before establishing a diagnosis, as biopsy may be precluded until further fluid accumulates. Treatment of the underlying cause – e.g. heart failure, pneumonia, pulmonary embolism or subphrenic abscess – will often be followed by resolution of the effusion. The management of pleural effusion in pneumonia, tuberculosis and malignancy is dealt with below.

**Empyema**

This is a collection of pus in the pleural space, which may be as thin as serous fluid or so thick that it is impossible to aspirate, even through a wide-bore needle. Microscopically, neutrophil leucocytes are present in large numbers. An empyema may involve the whole pleural space or only part of it (‘loculated’ or ‘encysted’ empyema) and is usually unilateral. It is always secondary to infection in a neighbouring structure, usually the lung, most commonly due to the bacterial pneumonias and tuberculosis. Over 40% of patients with community-acquired pneumonia develop an associated pleural effusion (‘parapneumonic’ effusion) and about 15% of these become secondarily infected. Other causes are infection of a haemothorax following trauma or surgery, oesophageal rupture, and rupture of a subphrenic abscess through the diaphragm.

Both pleural surfaces are covered with a thick, shaggy, inflammatory exudate. The pus in the pleural space is often under considerable pressure, and if the condition is not adequately treated, pus may rupture into a bronchus, causing a bronchopleural fistula and pyopneumothorax, or track through the chest wall with the formation of a subcutaneous abscess or sinus, so-called empyema necessitans.

**Clinical assessment**

An empyema should be suspected in patients with pulmonary infection if there is severe pleuritic chest pain or persisting or recurrent pyrexia, despite appropriate antibiotic treatment. In other cases, the primary infection may be so mild that it passes unrecognised and the first definite clinical features are due to the empyema itself. Once an empyema has developed, systemic features are prominent (Box 17.15).

**Investigations**

Chest X-ray appearances may be indistinguishable from those of pleural effusion, although pleural adhesions may confine the empyema to form a ‘D’-shaped shadow against the inside of the chest wall (Fig. 17.14). When air is present as well as pus (pyopneumothorax), a horizontal ‘fluid level’ marks the air/liquid interface. Ultrasound shows the position of the fluid, the extent of pleural thickening and whether fluid is in a single collection or multiloculated, containing fibrin and debris (Fig. 17.15). CT provides information on the pleura, underlying lung parenchyma and patency of the major bronchi.

Ultrasound or CT is used to identify the optimal site for aspiration, which is best performed using a wide-bore needle. If the fluid is thick and turbid pus, empyema is confirmed. Other features suggesting empyema are a fluid glucose of less than 3.3 mmol/L (60 mg/dL), lactate dehydrogenase (LDH) of more than 1000 IU/L, or a fluid pH of less than 7.0 (H⁺ > 100 nmol/L). However, pH measurement should be avoided if pus is thick, as it damages blood gas machines. The pus is frequently sterile on culture if antibiotics have already been given. The distinction between tuberculous and non-tuberculous disease can be difficult and may require pleural biopsy, histology, culture and/or a NAAT.

---

**17.14 Light’s criteria for distinguishing pleural transudate from exudate**

Exudate is likely if one or more of the following criteria are met:

- Pleural fluid protein:serum protein ratio > 0.5
- Pleural fluid LDH:serum LDH ratio > 0.6
- Pleural fluid LDH > two-thirds of the upper limit of normal serum LDH

(\(\text{LDH} = \text{lactate dehydrogenase}\))

**17.15 Clinical features of empyema**

**Systemic features**

- Pyrexia, usually high and remittent
- Rigors, sweating, malaise and weight loss
- Polymorphonuclear leucocytosis, high C-reactive protein

**Local features**

- Pleural pain; breathlessness; cough and sputum, usually because of underlying lung disease; copious purulent sputum if empyema ruptures into a bronchus (bronchopleural fistula)
- Clinical signs of pleural effusion

**Fig. 17.14 Chest X-ray showing a ‘D’-shaped shadow in the left mid-zone, consistent with an empyema. In this case, an intercostal chest drain has been inserted but the loculated collection of pus remains.**
Presenting problems in respiratory disease

• Preventing re-expansion of the lung. Surgery is also necessary if a bronchopleural fistula develops.

Despite the widespread availability of antibiotics that are effective against pneumonia, empyema remains a significant cause of morbidity and mortality.

Management

An empyema will heal only if infection is eradicated and the empyema space is obliterated, allowing apposition of the visceral and parietal pleural layers. This can only occur if re-expansion of the compressed lung is secured at an early stage by removal of all the pus from the pleural space. When the pus is sufficiently thin, this is most easily achieved by the insertion of a wide-bore intercostal tube into the most dependent part of the empyema space. If the initial aspirate reveals turbid fluid or frank pus, or if loculations are seen on ultrasound, the tube should be put on suction (−5 to −10 cmH₂O) and flushed regularly with 20 mL normal saline. If the organism causing the empyema can be identified, the appropriate antibiotic should be given for 2–4 weeks. Empirical antibiotic treatment (e.g. intravenous co-amoxiclav or cefuroxime with metronidazole) should be used if the organism is unknown. Intrapleural fibrinolytic therapy is of no benefit.

An empyema can often be aborted if these measures are started early, but if the intercostal tube is not providing adequate drainage – e.g. when the pus is thick or loculated – surgical intervention is required to clear the empyema cavity of pus and break down any adhesions. Surgical ‘decoration’ of the lung may also be required if gross thickening of the visceral pleura is preventing re-expansion of the lung. Surgery is also necessary if a bronchopleural fistula develops.

Despite the widespread availability of antibiotics that are effective against pneumonia, empyema remains a significant cause of morbidity and mortality.

Respiratory failure

The term ‘respiratory failure’ is used when pulmonary gas exchange fails to maintain normal arterial oxygen and carbon dioxide levels. Its classification into types I and II is defined by the absence or presence of hypercapnia (raised $P_{\text{aCO}_2}$).

Pathophysiology

When disease impairs ventilation of part of a lung (e.g. in asthma or pneumonia), perfusion of that region results in hypoxic and CO₂-laden blood entering the pulmonary veins. Increased ventilation of neighbouring regions of normal lung can increase CO₂ excretion, correcting arterial CO₂ to normal, but cannot augment oxygen uptake because the haemoglobin flowing through these normal regions is already fully saturated. Admixture of blood from the under-ventilated and normal regions thus results in hypoxia with normocapnia, which is called ‘type I respiratory failure’. Diseases causing this include all those that impair ventilation locally with sparing of other regions (Box 17.16).

Arterial hypoxia with hypercapnia (type II respiratory failure) is seen in conditions that cause generalised, severe ventilation–perfusion mismatch, leaving insufficient normal lung to correct $P_{\text{aCO}_2}$, or any disease that reduces total ventilation. The latter includes not just diseases of the lung but also disorders affecting any part of the neuromuscular mechanism of ventilation (Box 17.16).

Management of acute respiratory failure

Prompt diagnosis and management of the underlying cause is crucial. In type I respiratory failure, high concentrations of oxygen (40–60% by mask) will usually relieve hypoxia by increasing the alveolar $P_{\text{O}_2}$ in poorly ventilated lung units. Occasionally, however (e.g. severe pneumonia affecting several lobes), mechanical ventilation may be needed to relieve hypoxia. Patients who need high concentrations of oxygen for more than a few hours should receive humidified oxygen.

(ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)
Acute type II respiratory failure is an emergency requiring immediate intervention. It is useful to distinguish between patients with high ventilatory drive (rapid respiratory rate and accessory muscle recruitment) who cannot move sufficient air, and those with reduced or inadequate respiratory effort. In the former, particularly if inspiratory stridor is present, acute upper airway obstruction from foreign body inhalation or laryngeal obstruction (angioedema, carcinoma or vocal cord paralysis) must be considered, as the Heimlich manœuvre (p. 625), immediate intubation or emergency tracheostomy may be life-saving.

More commonly, the problem is in the lungs, with severe generalised bronchial obstruction from COPD or asthma, acute respiratory distress syndrome (ARDS) arising from a variety of insults (p. 198), or occasionally tension pneumothorax (p. 625). In all such cases, high-concentration (e.g. 80%) oxygen should be administered, pending a rapid examination of the respiratory system and measurement of arterial blood gases. Patients with the trachea deviated away from a silent and resonant hemithorax are likely to have tension pneumothorax, and air should be aspirated from the pleural space and a chest drain inserted as soon as possible. Patients with generalised wheeze, scanty breath sounds bilaterally or a history of asthma or COPD should be treated with salbutamol 2.5 mg nebulised with oxygen, repeated until bronchospasm is relieved. Failure to respond to initial treatment, declining conscious level and worsening respiratory acidosis (\( \text{H}^+ > 50 \text{ nmol/L} \) (\( \text{pH} < 7.3 \)), Pa\( \text{CO}_2 > 6.6 \) kPa (50 mmHg)) on blood gases are all indications that supported ventilation is required (p. 202).

A small percentage of patients with severe chronic COPD and type II respiratory failure develop abnormal tolerance to raised Pa\( \text{CO}_2 \) and may become dependent on hypoxic drive to breathe. In these patients only, lower concentrations of oxygen (24–28% by Venturi mask) should be used to avoid precipitating respiratory acidosis (\( \text{H}^+ > 50 \text{ nmol/L} \) (\( \text{pH} < 7.3 \)), Pa\( \text{CO}_2 > 6.6 \) kPa (50 mmHg)) on blood gases are all indications that supported ventilation is required (p. 202).

The principal aims of treatment in acute on chronic type II respiratory failure are to achieve a safe Pa\( \text{O}_2 > 7.0 \) kPa (52 mmHg)) without increasing Pa\( \text{CO}_2 \) and acidosis, while identifying and treating the precipitating condition. In these patients, it is not necessary to achieve a normal Pa\( \text{O}_2 \); even a small increase will greatly improve tissue oxygen delivery, since their Pa\( \text{O}_2 \) values are often on the steep part of the oxygen dissociation curve (see Fig. 10.9, p. 191). The risks of worsening hypercapnia and coma must be balanced against those of severe hypoxaemia, which include potentially fatal arrhythmias and hypoxic brain damage. Immediate treatment is shown in Box 17.17. Patients who are drowsy and have low respiratory drive require an urgent decision regarding intubation and ventilation, as this is likely to be the only effective treatment, even though weaning off the ventilator may be difficult in severe disease. The decision is challenging, and important factors to consider include patient and family wishes, presence of a potentially remediable precipitating condition, prior functional

### 17.17 Assessment and management of ‘acute on chronic’ type II respiratory failure

**Initial assessment**

- Patient may not appear distressed, despite being critically ill
  - Conscious level (response to commands, ability to cough)
  - CO\(_2\) retention (warm periphery, bounding pulses, flapping tremor)
  - Airways obstruction (wheeze, prolonged expiration, hyperinflation, intercostal indrawing, pursed lips)
  - Cor pulmonale (peripheral oedema, raised jugular venous pressure, hepatomegaly, ascites)
  - Background functional status and quality of life
  - Signs of precipitating cause (see Box 17.15)

**Investigations**

- Arterial blood gases (severity of hypoxaemia, hypercapnia, acidemia, bicarbonate)
- Chest X-ray

**Management**

- Maintenance of airway
- Treatment of specific precipitating cause
- Frequent physiotherapy ± pharyngeal suction
- Nebulised bronchodilators
- Controlled oxygen therapy:
  - Start with 24% Venturi mask
  - Aim for a Pa\( \text{O}_2 \) > 7 kPa (52 mmHg) (a Pa\( \text{O}_2 \) < 5 (37 mmHg) is dangerous)
- Antibiotics if evidence of infection
- Diuretics if evidence of fluid overload

**Progress**

- If Pa\( \text{O}_2 \) continues to rise or a safe Pa\( \text{O}_2 \) cannot be achieved without severe hypercapnia and acidemia, mechanical ventilatory support may be required
capacity and quality of life. The various types of non-invasive (via a face or nasal mask) or invasive (via an endotracheal tube) ventilation are detailed on page 202.

Respiratory stimulant drugs, such as doxapram, have been superseded by intubation and mechanical ventilation in patients with CO₂ narcosis.

Home ventilation for chronic respiratory failure

NIV is of great value in the long-term treatment of respiratory failure due to spinal deformity, neuromuscular disease and central alveolar hypoventilation. Some patients with advanced lung disease, e.g. cystic fibrosis, also benefit from NIV for respiratory failure. In these conditions, type II respiratory failure can develop slowly and insidiously. Morning headache (due to elevated PaCO₂) and fatigue are common symptoms but, in many cases, the diagnosis is revealed only by sleep studies or morning blood gas analysis. In the initial stages, ventilation is insufficient for metabolic needs only during sleep, when there is a physiological decline in ventilatory drive. Over time, however, CO₂ retention becomes chronic, with renal compensation of acidosis. Treatment by home-based NIV overnight is often sufficient to restore the daytime PaCO₂ to normal, and to relieve fatique and headache. In advanced disease (e.g. muscular dystrophies or cystic fibrosis), daytime NIV may also be required.

Lung transplantation

Lung transplantation is an established treatment for carefully selected patients with advanced lung disease unresponsive to medical therapy (Box 17.18). Single-lung transplantation may be used for selected patients with advanced emphysema or lung fibrosis. This is contraindicated in patients with chronic bilateral pulmonary infection, such as cystic fibrosis and bronchiectasis, because the transplanted lung is vulnerable to cross-infection in the context of post-transplant immunosuppression, and for these individuals bilateral lung transplantation is the standard procedure. Combined heart–lung transplantation is still occasionally needed for patients with advanced congenital heart disease, such as Eisenmenger’s syndrome, and is preferred by some surgeons for the treatment of primary pulmonary hypertension unresponsive to medical therapy.

The prognosis following lung transplantation is improving steadily with modern immunosuppressive drugs: over 50% 10-year survival in some UK centres. Chronic rejection with obliterative bronchiolitis continues to afflict some recipients, however. Glucocorticoids are used to manage acute rejection, but drugs that inhibit cell-mediated immunity specifically, such as ciclosporin, mycophenolate and tacrolimus (p. 89), are used to prevent chronic rejection. Azithromycin, statins and total lymphoid irradiation are employed to treat obliterative bronchiolitis but late organ failure remains a significant problem.

The major factor limiting the availability of lung transplantation is the shortage of donor lungs. To improve organ availability, techniques to recondition the lungs in vitro after removal from the donor are being developed.

Obstructive pulmonary diseases

Asthma

Asthma is a chronic inflammatory disorder of the airways, in which many cells and cellular elements play a role. Chronic inflammation is associated with airway hyper-responsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction within the lung that is often reversible, either spontaneously or with treatment.

The prevalence of asthma increased steadily over the latter part of last century. As asthma affects all age groups, it is one of the most common and important long-term respiratory conditions in terms of global years lived with disability (Fig. 17.16).

The development and course of asthma and the response to treatment are influenced by genetic determinants, while the rapid rise in prevalence implies that environmental factors are critically important in the development and expression of the disease. The potential role of indoor and outdoor allergens, microbial exposure, diet, vitamins, breastfeeding, tobacco smoke, air pollution and obesity have been explored but no clear consensus has emerged.

Fig. 17.16 The burden of asthma, measured by disability life years (DALYs) per 100 000 population. The burden of asthma is greatest in children approaching adolescence and the elderly. The burden is similar in males and females at ages below 30–34 but at older ages the burden is higher in males. From The Global Asthma Report 2014. Copyright 2014 The Global Asthma Network.
In some circumstances, the appearance of asthma is triggered by medications. Beta-blockers, even when administered topically

**Pathophysiology**

Airway hyper-reactivity (AHR) – the tendency for airways to narrow excessively in response to triggers that have little or no effect in normal individuals – is integral to the diagnosis of asthma and appears to be related, although not exclusively, to airway inflammation (Fig. 17.17). Other factors likely to be important in the behaviour of airway smooth muscle include the degree of airway narrowing and neurogenic mechanisms.

The relationship between atopy (the propensity to produce IgE) and asthma is well established and in many individuals there is a clear relationship between sensitisation and allergen exposure, as demonstrated by skin-prick reactivity or elevated serum-specific IgE. Common examples of allergens include house dust mites, pets such as cats and dogs, pests such as cockroaches, and fungi. Inhalation of an allergen into the airway is followed by an early and late-phase bronchoconstrictor response (Fig. 17.18). Allergic mechanisms are also implicated in some cases of occupational asthma (p. 613).

In cases of aspirin-sensitive asthma, the ingestion of salicylates results in inhibition of the cyc-oxygenase enzymes, preferentially shunting the metabolism of arachidonic acid through the lipoxygenase pathway with resultant production of the asthmogenic cysteiny1 leukotrienes. In exercise-induced asthma, hyperventilation results in water loss from the pericellular lining fluid of the respiratory mucosa, which, in turn, triggers mediator release. Heat loss from the respiratory mucosa may also be important.

In persistent asthma, a chronic and complex inflammatory response ensues, characterised by an influx of numerous inflammatory cells, the transformation and participation of airway structural cells, and the secretion of an array of cytokines, chemokines and growth factors. Examination of the inflammatory cell profile in induced sputum samples demonstrates that, although asthma is predominantly characterised by airway eosinophilia, neutrophilic inflammation predominates in some patients while in others scant inflammation is observed: so-called ‘pauci-granulocytic’ asthma.

**Clinical features**

Typical symptoms include recurrent episodes of wheezing, chest tightness, breathlessness and cough. Asthma is commonly mistaken for a cold or a persistent chest infection (e.g. longer than 10 days). Classical precipitants include exercise, particularly in cold weather, exposure to airborne allergens or pollutants, and viral upper respiratory tract infections. Wheeze apart, there is often very little to find on examination. An inspection for nasal polyps and eczema should be performed. Rarely, a vasculitic rash may suggest eosinophilic granulomatosis with polyangiitis (formerly known as Churg–Strauss syndrome; p. 1043).

Patients with mild intermittent asthma are usually asymptomatic between exacerbations. Individuals with persistent asthma report ongoing breathlessness and wheeze but these are variable, with symptoms fluctuating over the course of one day, or from day to day or month to month.

Asthma characteristically displays a diurnal pattern, with symptoms and lung function being worse in the early morning. Particularly when poorly controlled, symptoms such as cough and wheeze disturb sleep. Cough may be the dominant symptom in some patients, and the lack of wheeze or breathlessness may lead to a delay in reaching the diagnosis of so-called “cough-variant asthma”.

Some patients with asthma have a similar inflammatory response in the upper airway. Careful enquiry should be made as to a history of sinusitis, sinus headache, a blocked or runny nose and loss of sense of smell.

Although the aetiology of asthma is often elusive, an attempt should be made to identify any agents that may contribute to the appearance or aggravation of the condition. Particular enquiry should be made about potential allergens, such as exposure to a pet cat, guinea pig, rabbit or horse, pest infestation, exposure to moulds following water damage to a home or building, and any potential occupational agents (p. 613).

In some circumstances, the appearance of asthma is triggered by medications. Beta-blockers, even when administered topically
as eye drops, may induce bronchospasm, as may aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs). The classical aspirin-sensitive patient is female and presents in middle age with asthma, rhinosinusitis and nasal polyps. Aspirin-sensitive patients may also report symptoms following alcohol and foods containing salicylates. Other medications implicated include the oral contraceptive pill, cholinergic agents and prostaglandin F2α. Betel nuts contain arecoline, which is structurally similar to methacholine and can aggravate asthma. An important minority of patients develop a particularly severe form of asthma and this appears to be more common in women. Allergic triggers are less important and airway neutrophilia predominates.

**Diagnosis**

The diagnosis of asthma is predominantly clinical and is based on the combination of the history, lung function and ‘other’ tests, which allows high, intermediate or low probability of asthma to emerge. The approach may vary from patient to patient and may need to be re-evaluated following the introduction of treatment.

Supportive evidence is provided by the demonstration of variable airflow obstruction, preferably by using spirometry (Box 17.19) to measure FEV₁ and FVC. This identifies the obstructive defect, defines its severity, and provides a baseline for bronchodilator reversibility (Fig. 17.19). If spirometry is not available, a peak flow meter may be used. Symptomatic patients should be instructed to record peak flow readings after rising in the morning and before retiring in the evening. A diurnal variation in PEF of more than 20% (the lowest values typically being recorded in the morning) is considered diagnostic, and the magnitude of variability provides some indication of disease severity (Fig. 17.20). A trial of glucocorticoids (e.g. 30 mg daily for 2 weeks) may be useful in establishing the diagnosis, by demonstrating an improvement in either FEV₁ or PEF.

It is not uncommon for patients whose symptoms are suggestive of asthma to have normal lung function. In these circumstances, the demonstration of AHR by challenge tests may be useful to confirm the diagnosis (see Fig. 17.17). AHR has a high negative predictive value but positive results may be seen in other conditions, such as COPD, bronchiectasis and cystic fibrosis. The use of exercise tests is useful when symptoms are predominantly related to exercise (Fig. 17.21).

The diagnosis may be supported by the presence of atopy demonstrated by skin-prick tests or measurement of total and allergen-specific IgE, an FENO (a surrogate of eosinophilic airway inflammation) of ≥40 parts per billion in a glucocorticoid-naïve adult, or a peripheral blood eosinophilia. Chest X-ray appearances are often normal but lobar collapse may be seen if mucus occludes a large bronchus and, if accompanied by the presence of fitting infiltrates, may suggest that asthma has been complicated by allergic bronchopulmonary aspergillosis (p. 596). A high-resolution CT scan (HRCT) may be useful to detect bronchiectasis.

**Management**

**Setting goals**

Asthma is a chronic condition but may be controlled with appropriate treatment in the majority of patients. The goal of treatment should be to obtain and maintain complete control (Box 17.20) but aims may be modified according to the circumstances

---

**Box 17.19 How to make a diagnosis of asthma**

Compatible clinical history plus either/or:

- FEV₁ ≥12% (and 200 mL) increase following administration of a bronchodilator/trial of glucocorticoids. Greater confidence is gained if the increase is >15% and >400 mL.
- >20% diurnal variation on ≥3 days in a week for 2 weeks on PEF diary
- FEV₁ ≥15% decrease after 6 mins of exercise

(FEV₁ = forced expiratory volume in 1 sec; PEF = peak expiratory flow)

---

**Fig. 17.19 Reversibility test.** Forced expiratory manoeuvres before and 20 minutes after inhalation of a β₂-adrenoceptor agonist. Note the increase in forced expiratory volume in 1 second (FEV₁) from 1.0 to 2.5 L.

---

![Image](https://via.placeholder.com/150)

**Fig. 17.20 Serial recordings of peak expiratory flow (PEF) in a patient with asthma.** Note the sharp overnight fall (morning dip) and subsequent rise during the day. Following the introduction of glucocorticoids, there is an improvement in PEF rate and reduction of morning dipping.
pet, may effect improvement. House dust mite exposure may be minimised by replacing carpets with floorboards and using mite-impermeable bedding. So far, improvements in asthma control following such measures have been difficult to demonstrate. Many patients are sensitised to several ubiquitous aeroallergens, making avoidance strategies largely impractical. Measures to reduce fungal exposure may be applicable in specific circumstances and medications known to precipitate or aggravate asthma should be avoided. Smoking cessation (p. 94) is particularly important, as smoking not only encourages sensitisation but also induces a relative glucocorticoid resistance in the airway.

The stepwise approach to the management of asthma
See Figure 17.22.

Step 1: Occasional use of inhaled short-acting \(\beta_2\)-adrenoreceptor agonist bronchodilators
A variety of different inhaled devices are available and the choice of device should be guided by patient preference and competence.

![Fig. 17.21 Exercise-induced asthma. Serial recordings of forced expiratory volume in 1 second (FEV₁) in a patient with bronchial asthma before and after 6 minutes of strenuous exercise. Note initial rise on completion of exercise, followed by sudden fall and gradual recovery. Adequate warm-up exercise or pre-treatment with a \(\beta_2\)-adrenoceptor agonist, nedocromil sodium or a leukotriene antagonist can protect against exercise-induced symptoms.](image-url)

(IFEV₁ = forced expiratory volume in 1 sec; PEF = peak expiratory flow)
Obstructive pulmonary diseases

Fig. 17.22 Management approach in adults based on asthma control. (ICS = inhaled corticosteroids (glucocorticoids); LABA = long-acting β₂-agonist; LAMA = long-acting muscarinic antagonist; LTRA = leukotriene receptor antagonist; SR = sustained-release) From British Thoracic Society and SIGN guideline 153: British guideline on the management of asthma (2016).

Fig. 17.23 How to use a metered-dose inhaler.

Remove the cap and shake the inhaler
Breathe out gently and place the mouthpiece into the mouth
Incline the head backwards to minimise oropharyngeal deposition
Simultaneously, begin a slow deep inspiration, depress the canister and continue to inhale
Hold the breath for 10 seconds

For patients with mild intermittent asthma (symptoms less than once a week for 3 months and fewer than two nocturnal episodes per month), it is usually sufficient to prescribe an inhaled short-acting β₂-agonist, such as salbutamol or terbutaline, to be used as required. However, many patients (and their physicians) under-estimate the severity of asthma. A history of a severe exacerbation should lead to a step-up in treatment.

Step 2: Introduction of regular preventer therapy
Regular anti-inflammatory therapy (preferably inhaled glucocorticoids (ICS), such as beclometasone, budesonide (BUD), fluticasone, mometasone or ciclesonide) should be started in addition to inhaled β₂-agonists taken on an as-required basis for any patient who:
- has experienced an exacerbation of asthma in the last 2 years
- uses inhaled β₂-agonists three times a week or more
- reports symptoms three times a week or more
- is awakened by asthma one night per week.

For adults, a reasonable starting dose is 400 μg beclometasone dipropionate (BDP) or equivalent per day in adults, although higher doses may be required in smokers. Alternative but much less effective preventive agents include chromones, leukotriene receptor antagonists and theophyllines.

Step 3: Add-on therapy
If a patient remains poorly controlled despite regular use of an inhaled glucocorticoid, a thorough review should be undertaken of adherence, inhaler technique and ongoing exposure to modifiable aggravating factors. A further increase in the dose of inhaled glucocorticoid may benefit some patients but, in general, add-on therapy should be considered in adults taking 800 μg/day BDP (or equivalent).

The addition of a long-acting β₂-agonist (LABA) to an inhaled glucocorticoid provides more effective asthma control compared with increasing the dose of inhaled glucocorticoid alone. Fixed-combination inhalers of glucocorticoids and LABAs have been developed; these are more convenient, increase adherence and prevent patients using a LABA as monotherapy – the latter may be accompanied by an increased risk of life-threatening attacks.
or asthma death. The onset of action of formoterol is similar to that of salbutamol such that, in carefully selected patients, a fixed combination of budesonide and formoterol may be used as both rescue and maintenance therapy.

Oral leukotriene receptor antagonists (e.g. montelukast 10 mg daily) are generally less effective than LABAs as add-on therapy but may facilitate a reduction in the dose of inhaled glucocorticoid and control exacerbations.

Step 4: Poor control on moderate dose of inhaled glucocorticoid and add-on therapy: addition of a fourth drug
In adults, the dose of inhaled glucocorticoid may be increased to 2000 μg BDP/BUD (or equivalent) daily. A nasal glucocorticoid preparation should be used in patients with prominent upper airway symptoms. Leukotriene receptor antagonists, long-acting antimuscarinic agents, theophyllines or a slow-release β₂-agonist may be considered. If the trial of add-on therapy is ineffective, it should be discontinued.

Step 5: Continuous or frequent use of oral glucocorticoids
At this stage, prednisolone therapy (usually administered as a single daily dose in the morning) should be prescribed in the lowest amount necessary to control symptoms. Patients who are on long-term glucocorticoid tablets (>3 months) or are receiving more than three or four courses per year will be at risk of systemic side-effects (p. 670). The risk of osteoporosis in this group can be reduced by giving bisphosphonates (p. 1047). In patients who continue to experience symptoms and asthma exacerbation and demonstrate impaired lung function despite step 5 treatment, omalizumab, a monoclonal antibody directed against IgE, should be considered for those with a prominent atopic phenotype, and mepolizumab, a monoclonal antibody that blocks the binding of IL-5 to its receptor on eosinophils, should be considered in those with eosinophilic-mediated disease. The use of immunosuppressants, such as methotrexate, ciclosporin or oral gold, is less common nowadays, as the response is variable and the limited benefits may be easily offset by side-effects.

Step-down therapy
Once asthma control is established, the dose of inhaled (or oral) glucocorticoid should be titrated to the lowest dose at which effective control of asthma is maintained. Decreasing the dose of glucocorticoid by around 25–50% every 3 months is a reasonable strategy for most patients.

Exacerbations of asthma
The course of asthma may be punctuated by exacerbations with increased symptoms, deterioration in lung function, and an increase in airway inflammation. Exacerbations are most commonly precipitated by viral infections but moulds (Alternaria and Cladosporium), pollens (particularly following thunderstorms) and air pollution are also implicated. Most attacks are characterised by a gradual deterioration over several hours to days but some appear to occur with little or no warning: so-called brittle asthma. An important minority of patients appear to have a blunted perception of airway narrowing and fail to appreciate the early signs of deterioration.

Management of mild to moderate exacerbations
Doubling the dose of inhaled glucocorticoids does not prevent an impending exacerbation. Short courses of ‘rescue’ glucocorticoids (prednisolone 30–60 mg daily) are therefore often required to regain control. Tapering of the dose to withdraw treatment is not necessary, unless glucocorticoid has been given for more than 3 weeks.

Indications for ‘rescue’ courses include:
- symptoms and PEF progressively worsening day by day, with a fall of PEF below 60% of the patient’s personal best recording
- onset or worsening of sleep disturbance by asthma
- persistence of morning symptoms until midday
- progressively diminishing response to an inhaled bronchodilator
- symptoms that are sufficiently severe to require treatment with nebulised or injected bronchodilators.

Management of acute severe asthma
Box 17.22 highlights the immediate assessment requirements in acute asthma. Measurement of PEF is mandatory, unless the patient is too ill to cooperate, and is most easily interpreted when expressed as a percentage of the predicted normal or of the previous best value obtained on optimal treatment (Fig. 17.24). Arterial blood gas analysis is essential to determine the PaCO₂, a normal or elevated level being particularly dangerous. A chest X-ray is not immediately necessary, unless pneumothorax is suspected.

Treatment includes the following measures:
- Oxygen. High concentrations (humidified if possible) should be administered to maintain the oxygen saturation above 92% in adults. The presence of a high PaCO₂ should not be taken as an indication to reduce oxygen concentration but as a warning sign of a severe or life-threatening attack. Failure to achieve appropriate oxygenation is an indication for assisted ventilation.
- High doses of inhaled bronchodilators. Short-acting β₂-agonists are the agent of choice. In hospital, they are most conveniently given via a nebuliser driven by oxygen, but delivery of multiple doses of salbutamol via a metered-dose inhaler through a spacer device provides equivalent bronchodilatation and can be used in primary care. Ipratropium bromide provides further bronchodilator therapy and should be added to salbutamol in acute severe or life-threatening attacks.

### 17.22 Immediate assessment of acute severe asthma

#### Acute severe asthma
- PEF 33–50% predicted (<200 L/min)
- Heart rate ≥110 beats/min
- Respiratory rate ≥25 breaths/min
- Inability to complete sentences in 1 breath

#### Life-threatening features
- PEF <33% predicted (<100 L/min)
- SPO₂ <92% or PaO₂ < 8 kPa (60 mmHg) (especially if being treated with oxygen)
- Normal or raised PaCO₂
- Silent chest
- Cyanosis
- Feeble respiratory effort
- Bradycardia or arrhythmias
- Hypotension
- Exhaustion
- Deltirium
- Coma

#### Near-fatal asthma
- Raised PaCO₂ and/or requiring mechanical ventilation with raised inflation pressures

PEF = peak expiratory flow
Obstructive pulmonary diseases

Prior to discharge, patients should be stable on discharge medication (nebulised therapy should have been discontinued for at least 24 hours) and the PEF should have reached 75% of predicted or personal best. The acute attack should prompt a look for and avoidance of any trigger factors, the delivery of asthma education and the provision of a written self-management plan. The patient should be offered an appointment with a GP or asthma nurse within 2 working days of discharge, and follow-up at a specialist hospital clinic within a month.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is defined as a preventable and treatable disease characterised by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways.

**Systemic glucocorticoids.** These reduce the inflammatory response and hasten the resolution of an exacerbation. They should be administered to all patients with an acute severe attack. They can usually be administered orally as prednisolone but intravenous hydrocortisone may be used in patients who are vomiting or unable to swallow.

There is no evidence base for the use of intravenous fluids but many patients are dehydrated due to high insensible water loss and will probably benefit. Potassium supplements may be necessary, as repeated doses of salbutamol can lower serum potassium.

If patients fail to improve, a number of further options may be considered. Intravenous magnesium may provide additional bronchodilatation in patients whose presenting PEF is below 30% predicted. Some patients appear to benefit from the use of intravenous aminophylline but cardiac monitoring is recommended.

PEF should be recorded every 15–30 minutes and then every 4–6 hours. Pulse oximetry should ensure that $\text{SaO}_2$ remains above 92%, but repeat arterial blood gases are necessary if the initial $\text{PaCO}_2$ measurements were normal or raised, the $\text{PaO}_2$ was below 8 kPa (60 mmHg) or the patient deteriorates. Box 17.23 lists the indications for endotracheal intubation and intermittent positive pressure ventilation (IPPV).

**Prognosis**

The outcome from acute severe asthma is generally good but a considerable number of deaths occur in young people and many are preventable. Failure to recognise the severity of an attack, on the part of either the assessing physician or the patient, contributes to delay in delivering appropriate therapy and to under-treatment.

Prior to discharge, patients should be stable on discharge medication (nebulised therapy should have been discontinued for at least 24 hours) and the PEF should have reached 75% of predicted or personal best. The acute attack should prompt a look for and avoidance of any trigger factors, the delivery of asthma education and the provision of a written self-management plan. The patient should be offered an appointment with a GP or asthma nurse within 2 working days of discharge, and follow-up at a specialist hospital clinic within a month.

**17.23 Indications for assisted ventilation in acute severe asthma**

- Coma
- Respiratory arrest
- Deterioration of arterial blood gas tensions despite optimal therapy: $\text{PaO}_2 < 8 \text{kPa (60 mmHg)}$ and falling
- $\text{PaCO}_2 > 6 \text{kPa (45 mmHg)}$ and rising
- pH low and falling ($\text{H}^+ \text{ high and rising}$)
- Exhaustion, delirium, drowsiness

**MEASURE PEAK EXPIRATORY FLOW**

Convert PEF to % best or % predicted

**Fig. 17.24 Immediate treatment of patients with acute severe asthma.**
and the lung to noxious particles or gases. Exacerbations and co-morbidities contribute to the overall severity in individual patients. Related diagnoses include chronic bronchitis (cough and sputum for at least 3 consecutive months in each of 2 consecutive years) and emphysema (abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis). Extrapulmonary effects include weight loss and skeletal muscle dysfunction (Fig. 17.25). Commonly associated co-morbid conditions include cardiovascular disease, cerebrovascular disease, the metabolic syndrome (p. 730), osteoporosis, depression and lung cancer.

The prevalence of COPD is directly related to the prevalence of risk factors in the community, such as tobacco smoking, coal dust exposure or the use of biomass fuels, and to the age of the population being studied. Those with the most severe disease bear the greatest personal impact of the condition and contribute to its significant social and economic consequences on society. It is predicted that, by 2030, COPD will represent the seventh leading cause of disability and fourth most common cause of death worldwide.

Risk factors are shown in Box 17.24. Cigarette smoking represents the most significant risk factor for COPD and the risk of developing the condition relates to both the amount and duration of smoking. It is unusual to develop COPD with less than 10 pack years (1 pack year = 20 cigarettes/day/year) and not all smokers develop the condition, suggesting that individual susceptibility factors are important.

Pathophysiology

COPD has both pulmonary and systemic components (Fig. 17.25). The presence of airflow limitation combined with premature airway closure leads to gas trapping and hyperinflation, adversely affecting pulmonary and chest wall compliance. Pulmonary hyperinflation also results, which flattens the diaphragmatic muscles and leads to an increasingly horizontal alignment of the intercostal muscles, placing the respiratory muscles at a mechanical disadvantage. The work of breathing is therefore markedly increased – first on exercise, when the time for expiration is further shortened, but then, as the disease advances, at rest.

Fig. 17.25 The pulmonary and systemic features of chronic obstructive pulmonary disease.
Emphysema (Fig. 17.26) may be classified by the pattern of the enlarged airspaces: centriacinar, panacinar and paraseptal. Bullae form in some individuals. This results in impaired gas exchange and respiratory failure.

**Clinical features**

COPD should be suspected in any patient over the age of 40 years who presents with symptoms of chronic bronchitis and/or breathlessness. Depending on the presentation, important differential diagnoses include chronic asthma, tuberculosis, bronchiectasis and congestive cardiac failure.

Cough and associated sputum production are usually the first symptoms, and are often referred to as a ‘smoker’s cough’. Haemoptysis may complicate exacerbations of COPD but should not be attributed to COPD without thorough investigation.

Breathlessness usually prompts presentation to a health professional. The level should be quantified for future reference, often by documenting what the patient can manage before stopping; scales such as the modified Medical Research Council (MRC) dyspnoea scale may be useful (Box 17.25). In advanced disease, enquiry should be made as to the presence of oedema (which may be seen for the first time during an exacerbation) and morning headaches (which may suggest hypercapnia).

Physical signs (p. 546) are non-specific, correlate poorly with lung function, and are seldom obvious until the disease is advanced. Breath sounds are typically quiet; crackles may accompany infection but, if persistent, raise the possibility of bronchiectasis. Finger clubbing is not a feature of COPD and should trigger further investigation for lung cancer or fibrosis. Right heart failure may develop in patients with advanced COPD, particularly if there is coexisting sleep apnoea or thromboembolic disease (‘cor pulmonale’). However, even in the absence of heart failure, COPD patients often have pitting oedema from salt and water retention caused by renal hypoxia and hypercapnia. The term ‘cor pulmonale’ is a misnomer in such patients, as they do not have heart failure. Fatigue, anorexia and weight loss may point to the development of lung cancer or tuberculosis, but are common in patients with severe COPD and the body mass index (BMI) is of prognostic significance. Depression and anxiety are also common and contribute to morbidity.

Two classical phenotypes have been described: ‘pink puffers’ and ‘blue bloaters’. The former are typically thin and breathless, and maintain a normal PaCO₂ until the late stage of disease. The latter develop (or tolerate) hypercapnia earlier and may develop oedema and secondary polycythaemia. In practice, these phenotypes often overlap.

**Investigations**

Although there are no reliable radiographic signs that correlate with the severity of airflow limitation, a chest X-ray is essential to identify alternative diagnoses such as cardiac failure, other complications of smoking such as lung cancer, and the presence of bullae. A blood count is useful to exclude anaemia or document polycythaemia, and in younger patients with predominantly basal emphysema α₁-antitrypsin should be assayed.

The diagnosis requires objective demonstration of airflow obstruction by spirometry and is established when the post-bronchodilator FEV₁/FVC is <70%. The severity of COPD may be defined in relation to the post-bronchodilator FEV₁ (Box 17.26).

Measurement of lung volumes provides an assessment of hyperinflation. This is generally performed by helium dilution technique (p. 515); however, in patients with severe COPD, and in particular large bullae, body plethysmography is preferred because the use of helium may under-estimate lung volumes. The presence of emphysema is suggested by a low gas transfer coefficient (p. 515). Exercise tests provide an objective assessment of exercise tolerance and provide a baseline on which to judge the response to bronchodilator therapy or rehabilitation programmes; they may also be valuable when assessing prognosis. Pulse oximetry may prompt referral for a domiciliary oxygen assessment if less than 93%.

The assessment of health status by the St George’s Respiratory Questionnaire (SGRQ) is commonly used for research. In practice, the COPD Assessment Test and the COPD Control Questionnaire are easier to administer. HRCT is likely to play an increasing role in the assessment of COPD, as it allows the detection,
smokers, and cessation (p. 94) remains the only strategy that impacts favourably on the natural history of COPD. Complete cessation is accompanied by an improvement in lung function and deceleration in the rate of FEV1 decline (Fig. 17.28). In regions where the indoor burning of biomass fuels is important, the introduction of non-smoking cooking devices or alternative fuels should be encouraged.

**Bronchodilators**

Bronchodilator therapy is central to the management of breathlessness. The inhaled route is preferred and a number of different agents delivered by a variety of devices are available. Choice should be informed by patient preference and inhaler assessment. Short-acting bronchodilators may be used for patients with mild disease but longer-acting bronchodilators are usually more appropriate for those with moderate to severe disease. Significant improvements in breathlessness may be reported despite minimal changes in FEV1, probably reflecting improvements in lung emptying that reduce dynamic hyperinflation and ease the work of breathing. Oral bronchodilator therapy, such as theophylline preparations, may be contemplated in patients who cannot use inhaled devices efficiently but their use may be limited by side-effects, unpredictable metabolism and drug interactions; hence the requirement to monitor plasma levels. Orally active, highly selective phosphodiesterase inhibitors remain under appraisal.

**Combined inhaled glucocorticoids and bronchodilators**

The fixed combination of an inhaled glucocorticoid and a LABA improves lung function, reduces the frequency and severity of exacerbations and improves quality of life. These advantages may be accompanied by an increased risk of pneumonia, particularly in the elderly. LABA/inhaled glucocorticoid combinations are frequently given with a long-acting muscarinic antagonist (LAMA). LAMAs should be used with caution in patients with significant heart disease or a history of urinary retention.

**Oral glucocorticoids**

Oral glucocorticoids are useful during exacerbations but maintenance therapy contributes to osteoporosis and impaired skeletal muscle function, and should be avoided.

---

**Assessment of severity**

The severity of COPD has traditionally been defined in relation to the FEV1% predicted. However, assessing the impact of COPD on individual patients in terms of the symptoms and limitations in activity that they experience and whether they suffer frequent or significant exacerbations may provide a more clinically relevant assessment and help guide management.

**Management**

The management of COPD focuses on improving breathlessness, reducing the frequency and severity of exacerbations, and improving health status and prognosis.

**Reducing exposure to noxious particles and gases**

Sustained smoking cessation in mild to moderate COPD is accompanied by a reduced decline in FEV1 compared to persistent smokers, and cessation (p. 94) remains the only strategy that impacts favourably on the natural history of COPD. Complete cessation is accompanied by an improvement in lung function and deceleration in the rate of FEV1 decline (Fig. 17.28). In regions where the indoor burning of biomass fuels is important, the introduction of non-smoking cooking devices or alternative fuels should be encouraged.

**Bronchodilators**

Bronchodilator therapy is central to the management of breathlessness. The inhaled route is preferred and a number of different agents delivered by a variety of devices are available. Choice should be informed by patient preference and inhaler assessment. Short-acting bronchodilators may be used for patients with mild disease but longer-acting bronchodilators are usually more appropriate for those with moderate to severe disease. Significant improvements in breathlessness may be reported despite minimal changes in FEV1, probably reflecting improvements in lung emptying that reduce dynamic hyperinflation and ease the work of breathing. Oral bronchodilator therapy, such as theophylline preparations, may be contemplated in patients who cannot use inhaled devices efficiently but their use may be limited by side-effects, unpredictable metabolism and drug interactions; hence the requirement to monitor plasma levels. Orally active, highly selective phosphodiesterase inhibitors remain under appraisal.

**Combined inhaled glucocorticoids and bronchodilators**

The fixed combination of an inhaled glucocorticoid and a LABA improves lung function, reduces the frequency and severity of exacerbations and improves quality of life. These advantages may be accompanied by an increased risk of pneumonia, particularly in the elderly. LABA/inhaled glucocorticoid combinations are frequently given with a long-acting muscarinic antagonist (LAMA). LAMAs should be used with caution in patients with significant heart disease or a history of urinary retention.

**Oral glucocorticoids**

Oral glucocorticoids are useful during exacerbations but maintenance therapy contributes to osteoporosis and impaired skeletal muscle function, and should be avoided. Oral
glucocorticoid trials assist in the diagnosis of asthma but do not predict response to inhaled glucocorticoids in COPD.

**Pulmonary rehabilitation**

Exercise should be encouraged at all stages and patients reassured that breathlessness, while distressing, is not dangerous. Multidisciplinary programmes that incorporate physical training, disease education and nutritional counselling reduce symptoms, improve health status and enhance confidence. Most programmes include two to three sessions per week, last between 6 and 12 weeks, and are accompanied by demonstrable and sustained improvements in exercise tolerance and health status.

**Oxygen therapy**

Long-term domiciliary oxygen therapy (LTOT) improves survival in selected patients with COPD complicated by severe hypoxaemia (arterial PaO₂ < 7.3 kPa (55 mmHg); Box 17.27). It is most conveniently provided by an oxygen concentrator and patients should be instructed to use oxygen for a minimum of 15 hours/day; greater benefits are seen in those who use it for more than 20 hours/day. The aim of therapy is to increase the PaO₂ to at least 8 kPa (60 mmHg) or SaO₂ to at least 90%. Ambulatory oxygen therapy should be considered in patients who desaturate on exercise and show objective improvement in exercise capacity and/or dyspnoea with oxygen. Oxygen flow rates should be adjusted to maintain SaO₂ above 90%.

**Surgical intervention**

Bullectomy may be considered when large bullae compress surrounding normal lung tissue. Patients with predominantly upper lobe emphysema, preserved gas transfer and no evidence of pulmonary hypertension may benefit from lung volume reduction surgery (LVRS), in which peripheral emphysematous lung tissue is resected with the aim of reducing hyperinflation and decreasing the work of breathing. Both bullectomy and LVRS can be performed thorascopically, minimising morbidity. Lung transplantation may benefit carefully selected patients with advanced disease (p. 567).

**Other measures**

Patients with COPD should be offered an annual influenza vaccination and, as appropriate, pneumococcal vaccination. Obesity, poor nutrition, depression and social isolation should be identified and, if possible, improved. Mucolytic agents are occasionally used but evidence of benefit is limited.

**Palliative care**

Addressing end-of-life needs is an important, yet often ignored, aspect of care in advanced disease. Morphine preparations may be used for palliation of breathlessness in advanced disease and benzodiazepines in low dose may reduce anxiety. Decisions regarding resuscitation should be addressed in advance of critical illness.

### 17.28 Calculation of the BODE index

<table>
<thead>
<tr>
<th>Variable</th>
<th>Points on BODE index</th>
</tr>
</thead>
<tbody>
<tr>
<td>FEV₁ (forced expiratory volume in 1 sec)</td>
<td>0</td>
</tr>
<tr>
<td>Distance walked in 6 mins (m)</td>
<td>≥350</td>
</tr>
<tr>
<td>MRC dyspnoea scale*</td>
<td>0–1</td>
</tr>
<tr>
<td>Body mass index</td>
<td>&gt;21</td>
</tr>
</tbody>
</table>

*A patient with a BODE score of 0–2 has a mortality rate of around 10% at 52 months, whereas a patient with a BODE score of 7–10 has a mortality rate of around 80% at 52 months.

### Prognosis

COPD has a variable natural history but is usually progressive. The prognosis is inversely related to age and directly related to the post-bronchodilator FEV₁. Additional poor prognostic indicators include weight loss and pulmonary hypertension. A composite score (BODE), comprising the body mass index (B), the degree of airflow obstruction (O), a measurement of dyspnoea (D) and exercise capacity (E) may assist in predicting death from respiratory and other causes (Box 17.28). Respiratory failure, cardiac disease and lung cancer represent common modes of death.

### Acute exacerbations of COPD

Acute exacerbations of COPD are characterised by an increase in symptoms and deterioration in lung function and health status. They become more frequent as the disease progresses and are usually triggered by bacteria, viruses or a change in air quality. They may be accompanied by the development of respiratory failure and/or fluid retention and represent an important cause of death.

Many patients can be managed at home with the use of increased bronchodilator therapy, a short course of oral glucocorticoids and, if appropriate, antibiotics. The presence of cyanosis, peripheral oedema or an alteration in consciousness should prompt referral to hospital. In other patients, consideration of comorbidity and social circumstances may influence decisions regarding hospital admission.

### Oxygen therapy

In patients with an exacerbation of severe COPD, high concentrations of oxygen may cause respiratory depression and worsening acidosis (p. 566). Controlled oxygen at 24% or 28% should be used with the aim of maintaining a PaO₂ of more than 8 kPa (60 mmHg) (or an SaO₂ of more than 90%) without worsening acidosis.

### Bronchodilators

Nebulised short-acting β₂-agonists combined with an anticholinergic agent (e.g. salbutamol and ipratropium) should be administered. With careful supervision it is usually safe to drive nebulisers with oxygen, but if concern exists regarding oxygen sensitivity, they may be driven by compressed air and supplemental oxygen delivered by nasal cannula.
Glucocorticoids

Oral prednisolone reduces symptoms and improves lung function. Doses of 30 mg for 10 days are currently recommended but shorter courses may be acceptable. Prophylaxis against osteoporosis should be considered in patients who receive repeated courses of glucocorticoids (p. 670).

Antibiotic therapy

The role of bacteria in exacerbations remains controversial and there is little evidence for the routine administration of antibiotics. They are currently recommended for patients reporting an increase in sputum purulence, sputum volume or breathlessness. In most cases simple regimens are advised, such as an aminopenicillin, a tetracycline or a macrolide. Co-amoxiclav is only required in regions where β-lactamase-producing organisms are known to be common.

Non-invasive ventilation

Non-invasive ventilation is safe and effective in patients with an acute exacerbation of COPD complicated by mild to moderate respiratory acidosis (H+ >45 nmol/L, pH <7.35), and should be considered early in the course of respiratory failure to reduce the need for endotracheal intubation, treatment failure and mortality. It is not useful in patients who cannot protect their airway. Mechanical ventilation may be contemplated when there is a reversible cause for deterioration (e.g. pneumonia) or when no prior history of respiratory failure has been noted.

Additional therapy

Exacerbations may be accompanied by the development of peripheral oedema; this usually responds to diuretics. There has been a vogue for using an infusion of intravenous aminophylline but evidence for benefit is limited and attention must be paid to the risk of inducing arrhythmias and drug interactions. The use of the respiratory stimulant doxapram has been largely superseded by the development of NIV but it may be useful for a limited period in selected patients with a low respiratory rate.

Discharge

Discharge from hospital may be contemplated once patients are clinically stable on their usual maintenance medication. Hospital at-home teams may provide short-term nebuliser loan, improving discharge rates and providing additional support for the patient.

Bronchiectasis

Bronchiectasis means abnormal dilatation of the bronchi. Chronic suppurative airway infection with sputum production, progressive scarring and lung damage occur, whatever the cause.

Aetiology and pathology

Bronchiectasis may result from a congenital defect affecting airway ion transport or ciliary function, such as cystic fibrosis (see below), or may be acquired secondary to damage to the airways by a destructive infection, inhaled toxin or foreign body. The result is chronic inflammation and infection in the airways.

Box 17.30 shows the common causes, of which tuberculosis is the most common worldwide.

Localised bronchiectasis may occur due to the accumulation of pus beyond an obstructing bronchial lesion, such as enlarged tuberculous hilar lymph nodes, a bronchial tumour or an inhaled foreign body (e.g. an aspirated peanut).

The bronchiectatic cavities may be lined by granulation tissue, squamous epithelium or normal ciliated epithelium. There may also be inflammatory changes in the deeper layers of the bronchial wall and hypertrophy of the bronchial arteries. Chronic inflammatory and fibrotic changes are usually found in the surrounding lung tissue, resulting in progressive destruction of the normal lung architecture in advanced cases.

Clinical features

The symptoms are shown in Box 17.31.

Physical signs in the chest may be unilateral or bilateral. If the bronchiectatic airways do not contain secretions and there is no associated lobar collapse, there are no abnormal physical signs. When there are large amounts of sputum in the bronchiectatic spaces, numerous coarse crackles may be heard over the affected areas. Collapse with retained secretions blocking a proximal bronchus may lead to locally diminished breath sounds, while advanced disease may cause scarring and overlying bronchial

17.29 Obstructive pulmonary disease in old age

- Asthma: may appear de novo in old age, so airflow obstruction should not always be assumed to be due to COPD.
- Peak expiratory flow recordings: older people with poor vision have difficulty reading PEF meters.
- Perception of bronchoconstriction: impaired by age, so an older patient’s description of symptoms may not be a reliable indicator of severity.
- Stopping smoking: the benefits on the rate of loss of lung function decline with age but remain valuable up to the age of 80.
- Metered-dose inhalers: many older people cannot use these because of difficulty coordinating and triggering the device. Even mild cognitive impairment virtually precludes their use. Frequent demonstration and re-instruction in the use of all devices are required.
- Mortality rates for acute asthma: higher in old age, partly because patients under-estimate the severity of bronchoconstriction and also develop a lower degree of tachycardia and pulse paradoxus for the same degree of bronchoconstriction.
- Treatment decisions: advanced age in itself is not a barrier to intensive care or mechanical ventilation in an acute episode of asthma or COPD, but this decision may be difficult and should be shared with the patient (if possible), the relatives and the GP.

17.30 Causes of bronchiectasis

Congenital
- Cystic fibrosis
- Ciliary dysfunction syndromes:
  - Primary ciliary dyskinesia (immotile cilia syndrome)
  - Kartagener’s syndrome (sinusitis and transposition of the viscera)
- Primary hypogammaglobulinaemia (p. 79)

Acquired: children
- Severe infections in infancy (especially whooping cough, measles)
- Primary tuberculosis
- Inhaled foreign body

Acquired: adults
- Suppurative pneumonia
- Pulmonary tuberculosis
- Allergic bronchopulmonary aspergillosis complicating asthma (p. 596)
- Bronchial tumours
breathing. Acute haemoptysis is an important complication of bronchiectasis; management is described on page 560.

**Investigations**

In addition to common respiratory pathogens, sputum culture may reveal *Pseudomonas aeruginosa* and *Staphylococcus aureus*, fungi such as *Aspergillus* and various mycobacteria. Frequent cultures are necessary to ensure appropriate treatment of resistant organisms.

Bronchiectasis, unless very gross, is not usually apparent on a chest X-ray. In advanced disease, thickened airway walls, cystic bronchiectatic spaces and associated areas of pulmonary consolidation or collapse may be visible. CT is much more sensitive and shows thickened, dilated airways (Fig. 17.29).

A screening test can be performed in patients suspected of having a ciliary dysfunction syndrome by measuring the time taken for a small pellet of saccharin placed in the anterior chamber of the nose to reach the pharynx, at which point the patient can taste it. This time should not exceed 20 minutes but is greatly prolonged in patients with ciliary dysfunction. Ciliary beat frequency may also be assessed from biopsies taken from the nose. Structural abnormalities of cilia can be detected by electron microscopy.

**Management**

In patients with airflow obstruction, inhaled bronchodilators and glucocorticoids should be used to enhance airway patency.

**Physiotherapy**

Patients should be shown how to perform regular daily physiotherapy to assist the drainage of excess bronchial secretions. Efficiently executed, this is of great value both in reducing the amount of cough and sputum, and in preventing recurrent episodes of bronchopulmonary infection. Patients should lie in a position in which the lobe to be drained is uppermost. Deep breathing, followed by forced expiratory manoeuvres (the ‘active cycle of breathing’ technique), helps to move secretions in the dilated bronchi towards the trachea, from which they can be cleared by vigorous coughing. Devices that increase airway pressure either by a constant amount (positive expiratory pressure mask) or in an oscillatory manner (flutter valve) aid sputum clearance in some patients and a variety of techniques should be tried to find the one that suits the individual. The optimum duration and frequency of physiotherapy depend on the amount of sputum but 5–10 minutes twice daily is a minimum for most patients.

**Antibiotic therapy**

For most patients with bronchiectasis, the appropriate antibiotics are the same as those used in COPD (p. 578) but larger doses and longer courses are required, and resolution of symptoms is often incomplete. When secondary infection occurs with staphylococci and Gram-negative bacilli, in particular *Pseudomonas* species, antibiotic therapy becomes more challenging and should be guided by the microbiological sensitivities. For *Pseudomonas*, oral ciprofloxacin (500–750 mg twice daily) or an intravenous anti-pseudomonal β-lactam (e.g. piperacillin–tazobactam or ceftazidime) will be required. Haemoptysis in bronchiectasis often responds to treatment of the underlying infection, although percutaneous embolisation of the bronchial circulation by an interventional radiologist may be necessary in severe cases.

**Surgical treatment**

Excision of bronchiectatic areas is indicated in only a small proportion of cases. These are usually patients in whom the bronchiectasis is confined to a single lobe or segment on CT. Unfortunately, many of those in whom medical treatment proves unsuccessful are also unsuitable for surgery because of either extensive bilateral bronchiectasis or coexisting severe airflow obstruction. In progressive forms of bronchiectasis, resection of destroyed areas of lung that are acting as a reservoir of infection should be considered only as a last resort.

**Prognosis**

The disease is progressive when associated with ciliary dysfunction and cystic fibrosis, and eventually causes respiratory failure. In other patients, the prognosis can be relatively good if physiotherapy is performed regularly and antibiotics are used aggressively.

**Prevention**

As bronchiectasis commonly starts in childhood following measles, whooping cough or a primary tuberculous infection, adequate prophylaxis for and treatment of these conditions are essential. Early recognition and treatment of bronchial obstruction are also important.
### Cystic Fibrosis

#### Genetics, pathogenesis and epidemiology

Cystic fibrosis (CF) is the most common fatal genetic disease in Caucasians, with autosomal recessive inheritance, a carrier rate of 1 in 25, and an incidence of about 1 in 2500 live births (pp. 40 and 48). It is much less common in people of African descent and rarer still in Asians. CF is the result of mutations affecting a gene on the long arm of chromosome 7, which codes for a chloride channel known as cystic fibrosis transmembrane conductance regulator (CFTR); this influences salt and water movement across epithelial cell membranes. The most common CFTR mutation in northern European and American populations is ΔF508 but over 2000 mutations of this gene have now been identified. The genetic defect causes increased sodium and chloride content in sweat and increased resorption of sodium and water from respiratory epithelium (Fig. 17.30). Relative dehydration of the airway epithelium is thought to predispose to chronic bacterial infection and ciliary dysfunction, leading to bronchiectasis. The gene defect also causes disorders in the gut epithelium, pancreas, liver and reproductive tract (see below).

In the 1960s, few patients with CF survived childhood, yet with aggressive treatment of airway infection and nutritional support, life expectancy has improved dramatically, so that there are now more adults than children with CF in many developed countries. Until recently, the diagnosis was most commonly made from the clinical picture (bowel obstruction, failure to thrive, steatorrhoea and/or chest symptoms in a young child), supported by sweat electrolyte testing and genotyping. Patients with unusual phenotypes were commonly missed, however, and late diagnosis led to poorer outcomes. Neonatal screening for CF using immunoreactive trypsin and genetic testing of newborn blood samples is now routine in the UK and should reduce delayed diagnosis and improve outcomes. Pre-implantation and/or prenatal testing may be offered to those known to be at high risk (p. 56).

#### Clinical features

The lungs are macroscopically normal at birth, but bronchiolar inflammation and infections usually lead to bronchiectasis in childhood. At this stage, the lungs are most commonly infected with *Staph. aureus*; however, in adulthood, many patients become colonised with *P. aeruginosa*, *Stenotrophomonas maltophilia* or other Gram-negative bacilli. Recurrent exacerbations of bronchiectasis, initially in the upper lobes but subsequently throughout both lungs, cause progressive lung damage, resulting ultimately in death from respiratory failure. Other clinical manifestations are shown in Box 17.32. Most men with CF are infertile due to failure of development of the vas deferens, but microsurgical sperm aspiration and in vitro fertilisation are possible. Genotype is a poor predictor of disease severity in individuals; even siblings with matching genotypes may have different phenotypes. This suggests that other ‘modifier genes’, as yet unidentified, influence clinical outcome.

#### Management

**Treatment of CF lung disease**

The management of CF lung disease is that of severe bronchiectasis. All patients with CF who produce sputum should perform chest physiotherapy daily, and more frequently during exacerbations. While infections with *Staph. aureus* can often be managed with oral antibiotics, intravenous treatment (frequently self-administered at home through an implanted subcutaneous vascular access device) is usually needed for *Pseudomonas* infections.

Unfortunately, the bronchi of many patients with CF eventually become colonised with pathogens that are resistant to most antibiotics. Resistant strains of *P. aeruginosa*, *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are the main culprits and may require prolonged treatment with unusual combinations of antibiotics. *Aspergillus* and non-tuberculous mycobacteria are also frequently found in the sputum of patients with CF but in most cases these behave as benign ‘colonisers’ of the bronchiectatic airways and do not require specific therapy. An

---

**Fig. 17.30** Cystic fibrosis: basic defect in the pulmonary epithelium. **A** The cystic fibrosis gene (CFTR) codes for a chloride channel (1) in the apical (luminal) membrane of epithelial cells in the conducting airways. This is normally controlled by cyclic adenosine monophosphate (cAMP) and indirectly by β₂-adrenoceptor stimulation, and is one of several apical ion channels that control the quantity and solute content of airway-lining fluid. Normal channels appear to inhibit the adjacent epithelial sodium channels (2). **B** In cystic fibrosis, one of many cystic fibrosis gene defects causes absence or defective function of this chloride channel (3). This leads to reduced chloride secretion and loss of inhibition of sodium channels, with excessive sodium resorption (4) and dehydration of the airway lining. The resulting abnormal airway-lining fluid predisposes to infection by mechanisms still to be fully explained.
exception is Mycobacterium abscessus, which is multi-resistant, may be transmissible between patients with CF and can cause progressive lung destruction that is hard to treat.

Some patients have coexistent asthma, which is treated with inhaled bronchodilators and glucocorticoids; allergic bronchopulmonary aspergillosis (p. 596) also occurs occasionally in CF.

Four maintenance treatments have been shown to cause modest rises in lung function and/or to reduce the frequency of chest exacerbations in patients with CF (Box 17.33). Individual responses are variable and should be carefully monitored to avoid burdening patients with treatments that prove ineffective.

For advanced CF lung disease, home oxygen and NIV may be necessary to treat respiratory failure. Ultimately, lung transplantation can produce dramatic improvements but is limited by donor organ availability.

Treatment of non-respiratory manifestations of CF

There is a clear link between good nutrition and prognosis in CF. Malabsorption occurs in 85% of patients due to exocrine pancreatic failure and is treated with oral pancreatic enzymes and vitamin supplements. The increased calorie requirements of patients with CF are met by supplemental feeding, including nasogastric or gastrostomy tube feeding if required. Diabetes eventually develops in over 25% of patients and often requires insulin therapy. Osteoporosis secondary to malabsorption and chronic ill health should be sought and treated.

Novel therapies for cystic fibrosis

Small molecules designed to correct the function of particular CFTR defects are being developed. One such drug, ivacaftor (a CFTR ‘potentiator’), is now an established oral treatment for the 5% of patients with the G551D mutation, causing sustained improvements in FEV1 and weight, and normalising the sweat test. The combination of ivacaftor and lumacaftor (a CFTR ‘corrector’) has been found to have modest short-term benefit in patients with DF508 mutations. Improved versions of these treatments may soon offer similar benefits for these patients. Somatic gene therapy for CF is also under development. Manufactured normal copies of the CF gene are ‘packaged’ in liposomes or virus vectors and administered to the airways by aerosol inhalation. Trials are under way but more efficient gene delivery methods are needed to make this practical.

Infections of the respiratory system

Infections of the upper and lower respiratory tract are a major cause of morbidity and mortality, particularly in patients at the extremes of age and those with pre-existing lung disease or immune suppression.

Upper respiratory tract infection

Upper respiratory tract infections (URTIs), such as coryza (the common cold), acute pharyngitis and acute tracheobronchitis, are the most common of all communicable diseases and represent the most frequent cause of short-term absenteeism from work and school. The vast majority are caused by viruses (p. 249) and, in adults, are usually short-lived and rarely serious.

Acute coryza is the most common URTI and is usually the result of rhinovirus infection. In addition to general malaise, acute coryza typically causes nasal discharge, sneezing and cough. Involvement of the pharynx results in a sore throat, and that of...
the larynx a hoarse or lost voice. If complicated by a tracheitis or bronchitis, chest tightness and wheeze typical of asthma occur. Specific investigation is rarely warranted and treatment with simple analgesics, antipyretics and decongestants is all that is required. Symptoms usually resolve quickly, but if repeated URTIs ‘go to the chest’, a more formal diagnosis of asthma ought to be considered. A variety of viruses causing URTI may also trigger exacerbations of asthma or COPD and aggravate other lung diseases.

*Bordetella pertussis*, the cause of whooping cough, is an important source of URTI. It is highly contagious and is notifiable in the UK. Vaccination confers protection and is usually offered in infancy, but its efficacy wanes in adult life and the infection is easily spread. Adults usually experience a mild illness similar to acute coryza but some individuals develop paroxysms of coughing that can persist for weeks to months, earning whooping cough the designation of ‘the cough of 100 days’. The diagnosis may be confirmed by bacterial culture, polymerase chain reaction (PCR) from a nasopharyngeal swab or serological testing. If the illness is recognised early in the clinical course, macrolide antibiotics may ameliorate the course.

Rhinosinusitis typically causes a combination of nasal congestion, blockage or discharge and may be accompanied by facial pain/pressure or loss of smell. Examination usually confirms erythematous swollen nasal mucosa and pus may be evident. Nasal polyps should be sought and dental infection excluded. Treatment with topical glucocorticoids, nasal decongestants and regular nasal douching is usually sufficient and, although bacterial infection is often present, antibiotics are indicated only if symptoms persist for more than 5 days. Persistent symptoms or recurrent episodes should prompt a referral to an ear, nose and throat specialist.

Influenza is discussed on page 240.

### Pneumonia

Pneumonia is an acute respiratory illness associated with recently developed radiological pulmonary shadowing that may be segmental, lobar or multilobar. The context in which pneumonia develops is highly suggestive of the likely organism(s) involved; therefore, pneumonias are usually classified as community- or hospital-acquired, or those occurring in immunocompromised hosts. ‘Lobar pneumonia’ is a radiological and pathological term referring to homogeneous consolidation of one or more lung lobes, often with associated pleural inflammation; bronchopneumonia refers to more patchy alveolar consolidation associated with bronchial and bronchiolar inflammation, often affecting both lower lobes.

#### Community-acquired pneumonia

Figures from the UK suggest that an estimated 5–11/1000 adults suffer from community-acquired pneumonia (CAP) each year, accounting for around 5–12% of all lower respiratory tract infections. CAP may affect all age groups but is particularly common at the extremes of age; for example, worldwide, CAP continues to kill more children than any other illness and the propensity to ease the passing of the debilitated and the elderly led to designation of pneumonia as the ‘old man’s friend’.

Most cases are spread by droplet infection, and while CAP may occur in previously healthy individuals, several factors may impair the effectiveness of local defences and predispose to CAP (Box 17.35). *Streptococcus pneumoniae* (Fig. 17.31) remains the most common infecting agent, and thereafter the likelihood that other organisms may be involved depends on the age of the patient and the clinical context. Viral infections are recognised as important causes of CAP in children and their contribution to adult CAP is increasingly recognised. The common causative organisms are shown in Box 17.36.

#### Clinical features

Pneumonia, particularly lobar pneumonia, usually presents as an acute illness. Systemic features, such as fever, rigors, shivering and malaise, predominate and delirium may be present. The appetite is invariably lost and headache frequently reported.

Pulmonary symptoms include cough, which at first is characteristically short, painful and dry, but later is accompanied by the expectoration of mucopurulent sputum. Rust-coloured sputum may be produced by patients with *Strep. pneumoniae* infection and the occasional patient may report haemoptysis.
Melioidosis caused by *Burkholderia pseudomallei* is unusual in the UK, e.g. MERS-coronavirus (Middle East; p. 249), travel raises the possibility of infections that may otherwise be underdiagnosed. Recent foreign travel may be associated with exposure to specific bacteria (p. 618). Certain occupations following an episode of influenza.

**Clinical examination** should first focus on the respiratory and state, as these are important in forming a judgement as to severity of the illness (Fig. 17.32). Chest signs (p. 547) vary, depending on the inflammatory response, which proceeds through stages of acute exudation, red and then grey hepatisation, and finally resolution. When consolidated, the lung is typically dull to percussion and, as conduction of sound is enhanced, auscultation reveals bronchial breathing and whispering pectoriloquy; crackles are heard throughout. An assessment of the state of nutrition is important, particularly in the elderly. The presence of herpes labialis may point to streptococcal infection, as may the finding of ‘rusty’ sputum.

The differential diagnosis of pneumonia is shown in Box 17.37.

**Investigations**

The object of investigations, which are summarised in Box 17.38, is to confirm the diagnosis, assess the severity and identify the development of complications. While many cases of mild to moderate CAP can be successfully managed without identification of the organism, a range of microbiological tests should be performed on patients with severe CAP.

**Management**

The most important aspects of management include oxygenation, fluid balance and antibiotic therapy. In severe or prolonged illness, nutritional support may be required. Oxygen should be administered to all patients with tachypnoea, hypoxaemia, hypotension or acidosis with the aim of maintaining the \( P_{\text{a}O_2} \geq 8 \) kPa (60 mmHg) or \( \text{Sa}_O_2 \geq 92\% \). High concentrations (\( \geq 35\% \)), preferably humidified, should be used in all patients who do not have hypercapnia associated with COPD. Continuous positive airway pressure (CPAP) should be considered in those who remain hypoxic despite high-concentration oxygen therapy, and these patients should be managed in a high-dependency or intensive care environment where mechanical ventilation may be rapidly employed. Indications for ITU referral are summarised in Box 17.39.

**Fluid balance**

Intravenous fluids should be considered in those with severe illness, in older patients and those with vomiting. It may be appropriate to discontinue hypertensive agents temporarily. Otherwise, an adequate oral intake of fluid should be encouraged. Inotropic support may be required in patients with shock (p. 204).
Treatment of pleural pain

It is important to relieve pleural pain in order to allow the patient to breathe normally and cough efficiently. For the majority, simple analgesia with paracetamol, co-codamol or NSAIDs is sufficient. In some patients, opiates may be required but must be used with extreme caution in individuals with poor respiratory function.

Physiotherapy

Physiotherapy is not usually indicated in patients with CAP, although it may be helpful to assist expectoration in patients who suppress cough because of pleural pain.
**17.40 Antibiotic treatment for community-acquired pneumonia**

**Uncomplicated CAP**
- Amoxicillin 500 mg 3 times daily orally
- If patient is allergic to penicillin
  - Clarithromycin 500 mg twice daily orally or Erythromycin 500 mg 4 times daily orally
- If _Staphylococcus_ is cultured or suspected
  - Fluclouxacinil 1–2 g 4 times daily IV plus
  - Clarithromycin 500 mg twice daily IV
- If _Mycoplasma_ or _Legionella_ is suspected
  - Clarithromycin 500 mg twice daily orally or IV or Erythromycin 500 mg 4 times daily orally IV plus
  - Rifampicin 600 mg twice daily IV in severe cases

**Severe CAP**
- Clarithromycin 500 mg twice daily IV or Erythromycin 500 mg 4 times daily IV plus
- Co-amoxiclav 1.2 g 3 times daily IV or Ceftriaxone 1–2 g daily IV or Cefuroxime 1.5 g 3 times daily IV or
- Amoxicillin 1 g 4 times daily IV plus fluclouxacinil 2 g 4 times daily IV

*Antibiotic use in individual patients should take into account local guidance and antibiotic sensitivity patterns. Adapted from British Thoracic Society Guidelines.

---

**17.41 Complications of pneumonia**

- Para-pneumonic effusion – common
- Empyema (p. 564)
- Retention of sputum causing lobar collapse
- Deep vein thrombosis and pulmonary embolism
- Pneumothorax, particularly with _Staphylococcus aureus_
- Suppurative pneumonia/lung abscess
- ARDS, renal failure, multi-organ failure (p. 198)
- Ectopic abscess formation (_Staph. aureus_)
- Hepatitis, periarteritis, myocarditis, meningencephalitis
- Amythymias (e.g. atrial fibrillation)
- Pyrexia due to drug hypersensitivity

(ARDS = acute respiratory distress syndrome)

---

**Prognosis**

Most patients respond promptly to antibiotic therapy. Fever may persist for several days, however, and the chest X-ray often takes several weeks or even months to resolve, especially in old age. Delayed recovery suggests either that a complication has occurred (Box 17.41) or that the diagnosis is incorrect (see Box 17.37). Alternatively, the pneumonia may be secondary to a proximal bronchial obstruction or recurrent aspiration. The mortality rate of adults with non-severe pneumonia is very low (<1%); hospital death rates are typically between 5% and 10% but may be as high as 50% in severe illness.

**Discharge and follow-up**

The decision to discharge a hospitalised patient depends on the home circumstances and the likelihood of complications. A chest X-ray need not be repeated before discharge in patients making a satisfactory clinical recovery. Clinical review by GP or hospital should be arranged around 6 weeks later and a chest X-ray obtained if there are persistent symptoms, physical signs or reasons to suspect underlying malignancy.

---

**17.42 Factors predisposing to hospital-acquired pneumonia**

**Reduced host defences against bacteria**
- Reduced immune defences (e.g. glucocorticoid treatment, diabetes, malignancy)
- Reduced cough reflex (e.g. post-operative)
- Disordered mucociliary clearance (e.g. anaesthetic agents)
- Bulbar or vocal cord palsy

**Aspiration of nasopharyngeal or gastric secretions**
- Immobility or reduced conscious level
- Vomiting, dysphagia (N.B. stroke disease), achalasia or severe reflux
- Nasogastric intubation

**Bacteria introduced into lower respiratory tract**
- Endotracheal intubation/tracheostomy
- Infected ventilators/nebulisers/bronchoscopes
- Dental or sinus infection

**Bacteraemia**
- Abdominal sepsis
- Intravenous cannula infection
- Infected emboli

**Hospital-acquired pneumonia**

Hospital-acquired pneumonia (HAP) or nosocomial pneumonia refers to a new episode of pneumonia occurring at least 2 days after admission to hospital. It is the second most common hospital-acquired infection (HAI) and the leading cause of HAI-associated death. The elderly are particularly at risk, as are patients in intensive care units, especially when mechanically ventilated; here, the term ventilator-associated pneumonia (VAP) is applied. Health-care-associated pneumonia (HCAP) refers to the development of pneumonia in a person who has spent at least 2 days in hospital within the last 90 days, or has attended a haemodialysis unit, or received intravenous antibiotics, or been resident in a nursing home or other long-term care facility. The factors predisposing to the development of pneumonia in a hospitalised patient are listed in Box 17.42.

**Clinical features and investigation**

The diagnosis should be considered in any hospitalised or ventilated patient who develops purulent sputum (or endotracheal secretions), new radiological infiltrates, an otherwise unexplained increase in oxygen requirement, a core temperature >38.3°C, and a leucocytosis or leucopenia. The clinical features and radiographic signs are variable and non-specific, however, raising a broad differential diagnosis that includes pulmonary embolism, ARDS, pulmonary oedema, pulmonary haemorrhage and drug toxicity. Therefore, in contrast to CAP, microbiological confirmation should
be sought whenever possible. Adequate sputum samples may be difficult to obtain in the frail elderly person and physiotherapy should be considered to aid expectoration. In patients who are mechanically ventilated, bronchoscopy-directed protected brush specimens, bronchoalveolar lavage (BAL) or endotracheal aspirates may be obtained.

Management
The principles of management are similar to those of CAP, focusing on adequate oxygenation, appropriate fluid balance and antibiotics. The choice of empirical antibiotic therapy is considerably more challenging, however, given the diversity of pathogens and the potential for drug resistance.

The organisms implicated in early-onset HAP (occurring within 4–5 days of admission) are similar to those involved in CAP. In patients who have received no previous antibiotics, co-amoxiclav or cefuroxime represents a sensible choice. If the patient has received a course of recent antibiotics, then piperacillin/tazobactam or a third-generation cephalosporin should be considered.

Late-onset HAP is more often attributable to Gram-negative bacteria (e.g. Escherichia coli, Pseudomonas aeruginosa, Klebsiella spp. and Acinetobacter baumannii), Staph. aureus (including meticillin-resistant Staph. aureus (MRSA)) and anaerobes, and the choice of antibiotics ought to cover these possibilities. Antipseudomonal cover may be provided by a carbapenem (meropenem), an anti-pseudomonal cephalosporin or piperacillin–tazobactam. MRSA cover may be provided by glycopeptides such as vancomycin or linezolid. A. baumannii is usually sensitive to carbapenems but resistant cases may require nebulised and/or intravenous colistin. The choice of agents is most appropriately guided by knowledge of local patterns of microbiology and antibiotic resistance. It is sensible to commence broad-based cover, discontinuing less appropriate antibiotics as culture results become available. In the absence of good evidence, the duration of antibiotic therapy remains a matter for clinical judgement. Physiotherapy is important to aid expectoration in the immobile and elderly, and adequate nutritional support is often required.

Prevention
Despite appropriate management, the mortality from HAP is high (approximately 30%), mandating prevention whenever possible. Good hygiene is paramount, particularly with regard to hand-washing and any equipment used. Steps should be taken to minimise the chances of aspiration and to limit the use of stress ulcer prophylaxis with proton pump inhibitors. Oral antiseptic (chlorhexidine 2%) may be used to decontaminate the upper airway and some intensive care units employ selective decontamination of the digestive tract when the anticipated requirement for ventilation will exceed 48 hours.

Suppurative pneumonia, aspiration pneumonia and pulmonary abscesses
These conditions are considered together, as their aetiology and clinical features overlap. Suppurative pneumonia is characterised by destruction of the lung parenchyma by the inflammatory process. Although microabscess formation is a characteristic histological feature, ‘pulmonary abscess’ is usually taken to refer to lesions in which there is a large localised collection of pus, or a cavity lined by chronic inflammatory tissue, from which pus has escaped by rupture into a bronchus.

Suppurative pneumonia and pulmonary abscess often develop after the inhalation of septic material during operations on the nose, mouth or throat, under general anaesthesia, or of vomitus during anaesthesia or coma, particularly if oral hygiene is poor. Additional risk factors for aspiration pneumonia include bulbar or vocal cord palsy, achalasia or oesophageal reflux, and alcoholism. Aspiration tends to localise to dependent areas of the lung, such as the apical segment of the lower lobe in a supine patient. These conditions may also complicate local bronchial obstruction from a neoplasm or foreign body.

Infections are usually due to a mixture of anaerobes and aerobes in common with the typical flora encountered in the mouth and upper respiratory tract. Isolates of Prevotella melaninogenica, Fusobacterium necrophorum, anaerobic or microaerophilic cocci, and Bacteroides fragilis may be identified. When suppurative pneumonia or a pulmonary abscess occurs in a previously healthy lung, the most likely infecting organisms are Staph. aureus or K. pneumoniae. Actinomycosis infections (mostly A. israelii) cause chronic suppurative pulmonary infections, which may be associated with poor dental hygiene. Actinomycosis presents a particular diagnostic challenge because of the slow growth of actinomycetes.

Bacterial infection of a pulmonary infarct or a collapsed lobe may also produce a suppurative pneumonia or lung abscess. The organism(s) isolated from the sputum include Strep. pneumoniae, Staph. aureus, Streptococcus pyogenes, H. influenzae and, in some cases, anaerobic bacteria. In many cases, however, no pathogen can be isolated, particularly when antibiotics have been given.

Some strains of community-acquired MRSA (CA-MRSA) produce the cytotoxin Panton–Valentine leukocidin. The organism is mainly responsible for suppurative skin infection but may be associated with rapidly progressive severe necrotising pneumonia.

Lemierre’s syndrome is a rare cause of pulmonary abscesses. The usual causative agent is the anaerobe Fusobacterium necrophorum. The illness typically commences as a sore throat,
painful swollen neck, fever, rigor, haemoptysis and dyspnoea; spread into the jugular veins leads to thrombosis and metastatic dispersal of the organisms.

Injecting drug-users are at particular risk of developing haematogenous lung abscess, often in association with endocarditis affecting the pulmonary and tricuspid valves.

A non-infective form of aspiration pneumonia – exogenous lipid pneumonia – may follow the aspiration of animal, vegetable or mineral oils.

The clinical features of suppurative pneumonia are summarised in Box 17.44.

**Investigations**

Radiological features of suppurative pneumonia include homogeneous lobar or segmental opacity consistent with consolidation or collapse. Abscesses are characterised by cavititation and a fluid level. Occasionally, a pre-existing emphysematous bulla becomes infected and appears as a cavity containing an air–fluid level.

**Management**

Aspiration pneumonia can usually be treated with amoxicillin and metronidazole. Co-amoxiclav also has a suitable antibiotic spectrum but increases the risk of Clostridium difficile infection. Further modification of antibiotics should be informed by clinical response and microbiological results. CA-MRSA is usually susceptible to a variety of oral non-β-lactam antibiotics, such as trimethoprim/sulfamethoxazole, clindamycin, tetracyclines and linezolid. Parenteral therapy with vancomycin or linezolid can also be considered. Fusobacterium necrophorum is highly susceptible to β-lactam antibiotics and to metronidazole, clindamycin and third-generation cephalosporins. Prolonged treatment for 4–6 weeks may be required in some patients with lung abscess. Established pulmonary actinomycosis requires 6–12 months’ treatment with intravenous or oral penicillin, or with a tetracycline in penicillin-allergic patients.

Physiotherapy is of great value, especially when suppuration is present in the lower lobes or when a large abscess cavity has formed. In most patients there is a good response to treatment, and although residual fibrosis and bronchiectasis are common sequelae, these seldom give rise to serious morbidity. Surgery should be contemplated if no improvement occurs despite optimal medical therapy. Removal or treatment of any obstructing endobronchial lesion is essential.

**Clinical features**

These typically include fever, cough and breathlessness but are influenced by the degree of immunosuppression, and the presentation may be less specific in the more profoundly immunosuppressed. The onset of symptoms tends to be swift in those with a bacterial infection but more gradual in patients with opportunistic organisms such as Pneumocystis jirovecii and mycobacterial infections (p. 318). In P. jirovecii pneumonia, symptoms of cough and breathlessness can be present several days or weeks before the onset of systemic symptoms or the appearance of radiographic abnormality. The clinical features of invasive pulmonary aspergillosis are dealt with on page 597.

**Management**

In theory, treatment should be based on an established aetiological diagnosis; in practice, however, the causative agent is frequently unknown. Factors that favour a bacterial aetiology include neutropenia, rapid onset and deterioration. In these circumstances, broad-spectrum antibiotic therapy should be commenced immediately, e.g. a third-generation cephalosporin, or a quinolone, plus an antistaphylococcal antibiotic, or an antipseudomonal penicillin plus an aminoglycoside. Thereafter, treatment may be tailored according to the results of investigations and the clinical response. Depending on the clinical context and response to treatment, antifungal or antiviral therapies may be added. The management of P. jirovecii infection is detailed on page 318 and of invasive aspergillosis on page 596.
If these reparative processes fail, primary progressive disease ensues (Fig. 17.36). The estimated lifetime risk of developing disease after primary infection is 10%, with roughly half of this risk occurring in the first 2 years after infection. Factors predisposing to TB are summarised in Box 17.45 and the natural history of infection with TB is summarised in Box 17.46.

Clinical features: pulmonary disease

Primary pulmonary TB

Primary TB refers to the infection of a previously uninfected (tuberculin-negative) individual. A few patients develop a self-limiting febrile illness but clinical disease occurs only if there is a hypersensitivity reaction or progressive infection (Box 17.47). Progressive primary disease may appear during the course of the initial illness or after a latent period of weeks or months.

Miliary TB

Blood-borne dissemination gives rise to miliary TB, which may present acutely but more frequently is characterised by 2–3 weeks of fever, night sweats, anorexia, weight loss and a
and meningitis. Months or years later; few bacilli—tuberculous pleurisy and pleural effusion. (4) Blood-borne spread: the primary focus—progressive pulmonary tuberculosis. (3) Spread to the complex', which heals spontaneously in most cases. (2) Direct extension of primary focus to hilar and mediastinal lymph glands to form the 'primary 

![Fig. 17.36 Primary pulmonary tuberculosis.](image)

(1) Spread from the primary focus to hilar and mediastinal lymph glands to form the ‘primary complex’, which heals spontaneously in most cases. (2) Direct extension of the primary focus—progressive pulmonary tuberculosis. (3) Spread to the pleura—tuberculous pleurisy and pleural effusion. (4) Blood-borne spread: few bacilli—pulmonary, skeletal, renal, genitourinary infection, often months or years later; massive spread—miliary pulmonary tuberculosis and meningitis.

### Factors increasing the risk of tuberculosis

#### Patient-related

- Age (children > young adults < elderly)
- First-generation immigrants from high-prevalence countries
- Close contacts of patients with smear-positive pulmonary TB
- Overcrowding (prisons, collective dormitories); homelessness (doss houses and hostels)
- Chest X-ray evidence of self-healed TB
- Primary infection < 1 year previously
- Smoking: cigarettes, bidis (Indian cigarettes made of tobacco wrapped in temburini leaves) and cannabis

#### Associated diseases

- Immunosuppression: HIV, anti-tumour necrosis factor (TNF) and other biologic therapies, high-dose glucocorticoids, cytotoxic agents
- Malignancy (especially lymphoma and leukaemia)
- Diabetes mellitus
- Chronic kidney disease
- Tuberculosis
- Gastrointestinal disease associated with malnutrition (gastrectomy, jejuno-ileal bypass, cancer of the pancreas, malabsorption)
- Deficiency of vitamin D or A
- Recent measles in children

### Natural history of untreated primary tuberculosis

<table>

<tr>
<td>From 3 years onwards</td>
<td>Post-primary disease due to reactivation or re-infection</td>
</tr>
</tbody>
</table>

### Features of primary tuberculosis

#### Infection (4–8 weeks)

- Influenza-like illness
- Skin test conversion

#### Disease

- Lymphadenopathy: hilar (often unilateral), paratracheal or mediastinal
- Collapse (especially right middle lobe)
- Consolidation (especially right middle lobe)
- Obstructive emphysema
- Cavitation (rare)
- Pleural effusion
- Miliary
- Meningitis
- Pericarditis

#### Hypersensitivity

- Erythema nodosum
- Phlyctenular conjunctivitis
- Dactylitis

### Cryptic tuberculosis

- Age over 60 years
- Intermittent low-grade pyrexia of unknown origin
- Unexplained weight loss, general debility (hepatosplenomegaly in 25–50%)
- Normal chest X-ray
- Blood dyscrasias; leukaemoid reaction, pancytopenia
- Negative tuberculin skin test
- Confirmation by biopsy with granulomas and/or acid-fast bacilli in liver or bone marrow

Dry cough. Hepatosplenomegaly may develop and the presence of a headache may indicate coexistent tuberculous meningitis. Auscultation of the chest is frequently normal but in more advanced disease widespread cracks are evident. Fundoscopy may show choroidal tubercles. The classical appearances on chest X-ray are of fine 1–2 mm lesions (‘millet seed’) distributed throughout the lung fields, although occasionally the appearances are coarser. Anaemia and leucopenia reflect bone marrow involvement. ‘Cryptic’ miliary TB is an unusual presentation sometimes seen in old age (Box 17.48).

### Post-primary pulmonary TB

Post-primary disease refers to exogenous (‘new’ infection) or endogenous (reactivation of a dormant primary lesion) infection in a person who has been sensitised by earlier exposure. It is most frequently pulmonary and characteristically occurs in the apex of an upper lobe, where the oxygen tension favours survival of the strictly aerobic organism. The onset is usually insidious, developing slowly over several weeks. Systemic symptoms include fever, night sweats, malaise and loss of appetite and weight, and are accompanied by progressive pulmonary symptoms (Box 17.49). Very occasionally, this form of TB may present with one of the complications listed in Box 17.50. Radiological changes include ill-defined opacification in one or both of the upper lobes, and as progression occurs, consolidation, collapse and cavitation develop to varying degrees (Fig. 17.37). It is often difficult to distinguish active from quiescent disease on radiological criteria alone but the presence of a miliary pattern or cavitation favours active disease. In extensive disease, collapse may be marked and results in significant displacement of the trachea and mediastinum. Occasionally, a caseous lymph node may drain into an adjoining bronchus, leading to tuberculous pneumonia.
Gastrointestinal tuberculosis

TB can affect any part of the bowel and patients may present with a wide range of symptoms and signs (Fig. 17.38). Upper gastrointestinal tract involvement is rare and is usually an unexpected histological finding in an endoscopic or laparotomy specimen. Ileocaecal disease accounts for approximately half of abdominal TB cases. Fever, night sweats, anorexia and weight loss are usually prominent and a right iliac fossa mass may be palpable. Up to 30% of cases present with an acute abdomen. Ultrasound or CT may reveal thickened bowel wall, abdominal lymphadenopathy, mesenteric thickening or ascites. Barium enema and small bowel enema reveal narrowing, shortening and distortion of the bowel, with caecal involvement predominating. Diagnosis rests on obtaining histology by either colonoscopy or mini-laparotomy. The main differential diagnosis is Crohn’s disease (p. 813). Tuberculous peritonitis is characterised by abdominal distension, pain and constitutional symptoms. The ascitic fluid is exudative and cellular, with a predominance of lymphocytes. Laparoscopy reveals multiple white ‘tubercles’ over the peritoneal and omental surfaces. Low-grade hepatic dysfunction is common in miliary disease, in which biopsy reveals granulomas. Occasionally, patients may be frankly icteric, with a mixed hepatic/cholestasis picture.

Pericardial disease

Disease occurs in two forms (see Fig. 17.38 and p. 542): pericardial effusion and constrictive pericarditis. Fever and night sweats are rarely prominent and the presentation is usually insidious, with breathlessness and abdominal swelling. Coexistent pulmonary disease is very rare, with the exception of pleural effusion. Pulsus paradoxus, a raised JVP, hepatomegaly, prominent ascites and peripheral oedema are common to both types. Pericardial effusion is associated with increased pericardial dullness and a globular enlarged heart on chest X-ray, and pericardial calcification occurs in around 25% of cases. Constriction is associated with an early third heart sound and, occasionally, atrial fibrillation. Diagnosis is based on the clinical, radiological and echocardiographic findings (p. 542). The effusion is frequently blood-stained. Open pericardial biopsy can be performed where there is diagnostic uncertainty. The addition of glucocorticoids to antituberculosis treatment has been shown to help both forms of pericardial disease.

**Clinical features: extrapulmonary disease**

Extrapulmonary TB accounts for 20% of cases in those who are HIV-negative but is more common in HIV-positive patients.

**Lymphadenitis**

Lymph nodes are the most common extrapulmonary site of disease. Cervical and mediastinal glands are affected most frequently, followed by axillary and inguinal, and more than one region may be involved. Disease may represent primary infection, spread from contiguous sites or reactivation. Supraclavicular lymphadenopathy is often the result of spread from mediastinal disease. The nodes are usually painless and initially mobile but become matted together with time. When caseation and liquefaction occur, the swelling becomes fluctuant and may discharge through the skin with the formation of a ‘collar-stud’ abscess and sinus formation. Approximately half of cases fail to show any constitutional features, such as fevers or night sweats. The tuberculin test is usually strongly positive. During or after treatment, paradoxical enlargement, development of new nodes and suppuration may all occur but without evidence of continued infection; surgical excision is rarely necessary. In non-immigrant children in the UK, most mycobacterial lymphadenitis is caused by opportunistic mycobacteria, especially of the *M. avium* complex.

**Gastrointestinal tuberculosis**

TB can affect any part of the bowel and patients may present with a wide range of symptoms and signs (Fig. 17.38). Upper gastrointestinal tract involvement is rare and is usually an unexpected histological finding in an endoscopic or laparotomy specimen. Ileocaecal disease accounts for approximately half of abdominal TB cases. Fever, night sweats, anorexia and weight loss are usually prominent and a right iliac fossa mass may be palpable. Up to 30% of cases present with an acute abdomen. Ultrasound or CT may reveal thickened bowel wall, abdominal lymphadenopathy, mesenteric thickening or ascites. Barium enema and small bowel enema reveal narrowing, shortening and distortion of the bowel, with caecal involvement predominating. Diagnosis rests on obtaining histology by either colonoscopy or mini-laparotomy. The main differential diagnosis is Crohn’s disease (p. 813). Tuberculous peritonitis is characterised by abdominal distension, pain and constitutional symptoms. The ascitic fluid is exudative and cellular, with a predominance of lymphocytes. Laparoscopy reveals multiple white ‘tubercles’ over the peritoneal and omental surfaces. Low-grade hepatic dysfunction is common in miliary disease, in which biopsy reveals granulomas. Occasionally, patients may be frankly icteric, with a mixed hepatic/cholestasis picture.

Pericardial disease

Disease occurs in two forms (see Fig. 17.38 and p. 542): pericardial effusion and constrictive pericarditis. Fever and night sweats are rarely prominent and the presentation is usually insidious, with breathlessness and abdominal swelling. Coexistent pulmonary disease is very rare, with the exception of pleural effusion. Pulsus paradoxus, a raised JVP, hepatomegaly, prominent ascites and peripheral oedema are common to both types. Pericardial effusion is associated with increased pericardial dullness and a globular enlarged heart on chest X-ray, and pericardial calcification occurs in around 25% of cases. Constriction is associated with an early third heart sound and, occasionally, atrial fibrillation. Diagnosis is based on the clinical, radiological and echocardiographic findings (p. 542). The effusion is frequently blood-stained. Open pericardial biopsy can be performed where there is diagnostic uncertainty. The addition of glucocorticoids to antituberculosis treatment has been shown to help both forms of pericardial disease.
Central nervous system disease

Meningeal disease represents the most important form of central nervous system TB. Unrecognised and untreated, it is rapidly fatal. Even when appropriate treatment is prescribed, mortality rates of 30% have been reported, while survivors may be left with neurological sequelae. Clinical features, investigations and management are described on page 1120.

Bone and joint disease

The spine is the most common site for bony TB (Pott’s disease), which usually presents with chronic back pain and typically involves the lower thoracic and lumbar spine (see Fig. 17.38). The infection starts as a discitis and then spreads along the spinal ligaments to involve the adjacent anterior vertebral bodies, causing angulation of the vertebrae with subsequent kyphosis. Paravertebral and psoas abscess formation is common and the disease may present with a large (cold) abscess in the inguinal region. CT or MRI is valuable in gauging the extent of disease, the amount of cord compression, and the site for needle biopsy or open exploration, if required. The major differential diagnosis is malignancy, which tends to affect the vertebral body and leave the disc intact. Important complications include spinal instability or cord compression.

TB can affect any joint but most frequently involves the hip or knee. Presentation is usually insidious, with pain and swelling; fever and night sweats are uncommon. Radiological changes are often non-specific but, as disease progresses, reduction in joint space and erosions appear. Poncet’s arthropathy is an immunologically mediated polyarthritis that usually resolves within 2 months of starting treatment.

Genitourinary disease

Fever and night sweats are rare with renal tract TB and patients are often only mildly symptomatic for many years. Haematuria, frequency and dysuria are often present, with sterile pyuria found on urine microscopy and culture. In women, infertility from endometritis, or pelvic pain and swelling from salpingitis or a tubo-ovarian abscess occurs occasionally. In men, genitourinary TB may present as epididymitis or prostatitis.

Investigations

The presence of an otherwise unexplained cough for more than 2–3 weeks, particularly in regions where TB is prevalent, or typical chest X-ray or CT changes (Fig. 17.39) should prompt further investigation (Box 17.51). Direct microscopy of a sputum smear remains the most important first step. At least two sputum samples (including at least one obtained in the early morning) should be obtained. Induced sputum may be used in those unable to expectorate. In selected cases, bronchoscopy and lavage or aspiration of a lymph node by EBUS may be used.

Light-emitting diode fluorescent microscopy with auramine staining is increasingly replacing the more traditional standard light microscopy and Ziehl–Neelsen stain (Fig. 17.40) or the use of mercury-vapour fluorescent microscopy. A positive smear is sufficient for the presumptive diagnosis of TB but definitive
Diagnosis of tuberculosis

Specimens required

**Pulmonary**
- Sputum* (induced with nebulised hypertonic saline if patient not expectorating)
- Bronchoscopy with washings or BAL
- Gastric washing* (mainly used for children)

**Extrapulmonary**
- Fluid examination (cerebrospinal, ascitic, pleural, pericardial, joint): yield classically very low
- Tissue biopsy (from affected site): bone marrow/liver may be diagnostic in disseminated disease

Diagnostic tests

- Tuberculin skin test: low sensitivity/specificity; useful only in primary or deep-seated infection
- Stain
  - Ziehl–Neelsen
  - Auramine fluorescence
- Nucleic acid amplification
- Culture
  - Solid media (Löwenstein–Jensen, Middlebrook)
  - Liquid media (e.g. MGIT)
- Pleural fluid: adenosine deaminase
- Response to empirical antituberculous drugs (usually seen after 5–10 days)

Baseline blood tests

- Full blood count, C-reactive protein, erythrocyte sedimentation rate, urea and electrolytes, liver function tests

*At least two but preferably three, including an early morning sample.

The slow growth of MTB on solid (typically between 4 and 6 weeks) and automated and semi-automated liquid (typically around 2 weeks) culture media has prompted the development of rapid NAATs (p. 106). For example, Xpert MTB/RIF (a DNA detection-based NAAT) has the capacity to detect MTB (and rifampicin resistance) in less than 2 hours. However, while it is specific to MTB, it is not sufficiently sensitive to have replaced culture.

The diagnosis of extrapulmonary TB can be more challenging. There are generally fewer organisms (particularly in meningeal or pleural fluid), so culture, histopathological examination of tissue and/or NAAT may be required. Stimulation of T cells by mycobacterial antigens leads to increased levels of adenosine deaminase in pleural, pericardial, cerebrospinal and ascitic fluid, and so may assist in confirming suspected TB.

In the presence of HIV, examination of sputum may still be useful, as subclinical pulmonary disease is common. Lateral flow urinary lipoarabinomannan assay (LF-LAM) may be useful in the severely ill patient with a CD4 count of 100 cells/μL or less.

**Drug sensitivity testing**

The rapid detection of drug resistance is central both to the management of the individual with TB and to control of the disease in the population. The gold standard remains culture, in either solid or liquid media, but the use of other phenotypic tests, such as microscopically observed drug susceptibility (MODS), colorimetric redox indicator (CRI) methods and nitrate reductase assay, offer low-cost alternatives, depending on the resource and expertise available. The potential for molecular tests to provide rapid drug sensitivity testing (DST) is improving, particularly with regard to the detection of rifampicin resistance, which is important because rifampicin forms the cornerstone of 6-month chemotherapy. Rapid identification of rifampicin resistance is provided by Xpert MTB/RIF. Line probe assays (LPAs) use PCR and reverse hybridisation to detect genetic sequences linked to resistance to both rifampicin and isoniazid, and increasingly to resistance to pyrazinamide, ethambutol and other second-line agents.

**Management**

**Chemotherapy**

The treatment of TB is based on the principle of an initial intensive phase to reduce the bacterial population rapidly, followed by a continuation phase to destroy any remaining bacteria (Box 17.52). Standard treatment involves 6 months’ treatment with isoniazid and rifampicin, supplemented in the first 2 months with
Patients treated with rifampicin should be advised that their urine, tears and other secretions will develop a bright, orange/red coloration, and women taking the oral contraceptive pill must be warned that its efficacy will be reduced and alternative contraception may be necessary. Ethambutol and streptomycin should be used with caution in renal impairment, with appropriate dose reduction and monitoring of drug levels. Adverse drug reactions occur in about 10% of patients but are significantly more common with HIV co-infection (Box 17.53).

Baseline liver function and regular monitoring are important for patients treated with standard therapy. Rifampicin may cause asymptomatic hyperbilirubinaemia but, along with isoniazid and pyrazinamide, may also cause hepatitis. Mild asymptomatic increases in transaminases are common but significant hepatotoxicity only occurs in 2–5%. It is appropriate to stop treatment and allow any symptoms to subside and the liver function tests to recover before commencing a stepwise re-introduction of the individual drugs. Less hepatotoxic regimens may be considered, including streptomycin, ethambutol and fluoroquinolones.

Glucocorticoids reduce inflammation and limit tissue damage; they are currently recommended when treating pericardial or meningeal disease, and in children with endobronchial disease. They may confer benefit in TB of the ureter, pleural effusions and extensive pulmonary disease, and can suppress hypersensitivity drug reactions. Surgery should be considered in cases complicated by massive haemoptysis, loculated empyema, constrictive pericarditis, lymph node suppuration, and spinal disease with cord compression, but usually only after a full course of antituberculosis treatment.

The effectiveness of therapy for pulmonary TB is assessed by further sputum smear at 2 months and at 5 months. Treatment failure is defined as a positive sputum smear or culture at 5 months or any patient with a multidrug-resistant strain, regardless of
whether they are smear-positive or negative. Extrapulmonary TB must be assessed clinically or radiographically, as appropriate.

Control and prevention

TB is preventable, particularly so in those with latent TB. Supporting the development of laboratory and health-care services to improve detection and treatment of active and latent TB is an important component of this goal.

Detection of latent TB

The majority of individuals exposed to MTB harbour the bacteria, which remain dormant. They do not develop any signs of active disease and are non-infectious. They are however, at risk of developing active TB disease and becoming infectious. The lifetime risk of TB disease for a person with documented latent TB infection is estimated at 5–15%, with the majority of cases occurring within the first 5 years after initial infection.

Latent TB may be identified by the presence of immune responses to M. tuberculosis antigens. Contact tracing is a legal requirement in many countries. It has the potential to identify the probable index case, other cases infected by the same index patient (with or without evidence of disease), and close contacts who should receive BCG vaccination (see below) or chemotherapy. Approximately 10–20% of close contacts of patients with smear-positive pulmonary TB and 2–5% of those with smear-negative, culture-positive disease have evidence of TB infection.

Cases are commonly identified using the tuberculin skin test (TST; Fig. 17.41) or an IGRA (Fig. 17.42). An otherwise asymptomatic contact who tests positive but has a normal chest X-ray may be treated with chemoprophylaxis to prevent infection from progressing to clinical disease. Chemoprophylaxis should be offered to adults up to the age of 65 (although age-specific cut-off varies by country). It should also be considered for HIV-infected close contacts of a patient with smear-positive disease. A course of rifampicin and isoniazid for 3 months or isoniazid for 6 months is effective.

Tuberculin skin testing may be associated with false-positive reactions in those who have had a BCG vaccination and in areas where exposure to non-tuberculous mycobacteria is high. The skin tests may also be falsely negative in the setting of immunosuppression or overwhelming TB infection.

IGRAs detect the release of interferon-gamma (IFN-γ) from sensitised T cells in response to antigens, such as early secretory antigenic target (ESAT)-6 or culture filtrate protein (CFP)-10, which are encoded by genes specific to Mycobacterium tuberculosis and are not shared with BCG or opportunistic mycobacteria (Fig. 17.42). IGRAs are more specific than skin testing and logistically more convenient, as they require a single blood test rather than two clinic visits. In the UK, a dual strategy of TST followed by IGRA is recommended. TST remains the first choice in children, while IGRA represents the first choice for individuals with HIV.

Directly observed therapy

Poor adherence to therapy is a major factor in prolonged illness, risk of relapse, and the emergence of drug resistance. Directly observed therapy (DOT) involves the supervised administration of therapy 3 times weekly to improve adherence. DOT has become an important control strategy in resource-poor nations. In the UK, it is currently recommended for patients thought unlikely to be adherent to therapy: homeless people and drifters, alcohol or

---

**Fig. 17.41** The tuberculin skin test. A The reaction to the intradermal injection of tuberculin purified protein derivative (PPD) on the inner surface of the forearm is read between 48 and 72 hours. B The diameter of the indurated area should be measured across the forearm and is positive when ≥5 mm.

**Fig. 17.42** The principles of interferon-gamma release assays (IGRAs). A Sample of either (A) purified T cells (T-SPOT.TB test) or (B) whole blood (QuantIFERON–TB Gold test) is incubated in the presence of antigens specific to Mycobacterium tuberculosis (MTB). The release of interferon-gamma (IFN-γ) by the cells is measured by enzyme-linked immunosorbent assay (ELISA). (ELISPOT = enzyme-linked immunosorbent spot assay)
drug users, patients with serious mental illness and those with a history of non-adherence.

**TB and HIV/AIDS**

The close links between HIV and TB, particularly in sub-Saharan Africa, and the potential for both diseases to overwhelm healthcare funding in resource-poor nations have been recognised, with the promotion of programmes that link detection and treatment of TB with detection and treatment of HIV. It is recommended that all patients with TB should be tested for HIV infection. Mortality is high and TB is a leading cause of death in HIV patients. Full discussion of its presentation and management is given on page 318.

**Drug-resistant TB**

Drug-resistant TB is defined by the presence of resistance to any first-line agent. Multidrug-resistant tuberculosis (MDR-TB) is defined by resistance to at least rifampicin and isoniazid, with or without other drug resistance. Globally, an estimated 3.3% of new TB cases and 20% of previously treated cases have MDR-TB. In 2014, an estimated 190 000 people died of MDR-TB. Extensively drug-resistant tuberculosis (XDR-TB) is defined as resistance to at least rifampicin and isoniazid, in addition to any quinolone and at least one injectable second-line agent. An estimated 9.7% of people with MDR-TB have XDR-TB. The prevalence of MDR-TB is rising, particularly in the former Soviet Union, Central Asia and Africa. It is more common in individuals with a prior history of TB, particularly if treatment has been inadequate, and those with HIV infection. Box 17.54 lists the factors contributing to the emergence of drug-resistant TB. Diagnosis is challenging, especially in resource-poor settings, and although cure may be possible, it requires prolonged treatment with less effective, more toxic and more expensive therapies. The mortality rate from MDR-TB is high and that from XDR-TB higher still.

**Vaccines**

BCG (the Calmette–Guérin bacillus), a live attenuated vaccine derived from *M. bovis*, is the most established TB vaccine. It is administered by intradermal injection and is highly immunogenic. BCG appears to be effective in preventing disseminated disease, including tuberculous meningitis, in children, but its efficacy in adults is inconsistent and new vaccines are urgently needed. Current vaccination policies vary worldwide according to incidence and health-care resources, but usually target children and other high-risk individuals. BCG is very safe, with the occasional complication of local abscess formation. It should not be administered to those who are immunocompromised (e.g. by HIV) or pregnant.

**Prognosis**

Following successful completion of chemotherapy, cure should be anticipated in the majority of patients. There is a small (<5%) and unavoidable risk of relapse. Most relapses occur within 5 months and usually have the same drug susceptibility. In the absence of treatment, a patient with smear-positive TB will remain infectious for an average of 2 years; in 1 year, 25% of untreated cases will die. Death is more likely in those who are smear-positive and those who smoke. A few patients die unexpectedly soon after commencing therapy and it is possible that some have subclinical hypoaldrenism that is unmasked by a rifampicin-induced increase in glucocorticoid metabolism. HIV-positive patients have higher mortality rates and a modestly increased risk of relapse.

**Opportunistic mycobacterial infection**

Other species of environmental mycobacteria (often termed ‘atypical’) may cause human disease (Box 17.55). The sites commonly involved are the lungs, lymph nodes, skin and soft tissues. The most widely recognised of these mycobacteria, *M. avium* complex (MAC), is well described in severe HIV disease (CD4 count <50 cells/mL – p. 324). However, several others (including MAC) colonise and/or infect apparently immunocompetent patients with chronic lung diseases such as COPD, bronchiectasis, pneumoconiosis, old TB, or cystic fibrosis. The clinical presentation varies from a relatively indolent course in some to an aggressive course characterised by cavitary or nodular disease in others. Radiological appearances may be similar to classical TB, but in patients with bronchiectasis, opportunistic infection may present with lower-zone nodules. The most commonly reported organisms include *M. kansasi*, *M. malmoense*, *M. xenopi* and *M. abscessus* but geographical variation is marked. *M. abscessus* and *M. fortuitum* grow rapidly but the majority grow slowly. More rapid diagnostic systems are under development, including DNA probes, high-performance liquid chromatography (HPLC), PCR restriction enzyme analysis (RPA) and 16S rRNA gene sequence analysis. With the exception of *M. kansasi*, drug sensitivity testing is usually unhelpful in predicting treatment response. In the UK, these organisms are not notifiable to local public health departments as they are not normally communicable, although there is some evidence of patient-to-patient transmission of *M. abscessus* in cystic fibrosis.

**17.54 Site-specific opportunistic mycobacterial disease**

**Pulmonary**

- *M. xenopi*
- *M. kansasi*
- *M. malmoense*  
  - MAC  
  - *M. abscessus* (in cystic fibrosis)

**Lymph node**

- MAC  
- *M. malmoense*  
  - *M. fortuitum*  
  - *M. chelonei*

**Soft tissue/skin**

- *M. lepraes*  
- *M. ulcerans* (prevalent in Africa, northern Australia and South-east Asia)  
  - *M. marinum*  
  - *M. fortuitum*  
  - *M. chelonei*

**Disseminated**

- MAC (HIV-associated)  
- *M. haemophilum*  
- *M. genavense*  
- *M. scrofulaceum*  
- BCG  
- *M. fortuitum*  
- *M. chelonei*  
- *M. acrofaciale*  
- *M. intracellulare* and *M. avium*
Respiratory diseases caused by fungi

The majority of fungi encountered by humans are harmless saprophytes but in certain circumstances (Box 17.56) some species may cause disease by infecting human tissue, promoting damaging allergic reactions or producing toxins. 'Mycosis' is the term applied to disease caused by fungal infection. The conditions associated with Aspergillus species are listed in Box 17.57.

### Allergic bronchopulmonary aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) occurs as a result of a hypersensitivity reaction to germinating fungal spores in the airway wall. The condition may complicate the course of asthma and cystic fibrosis, and is a recognised cause of pulmonary eosinophilia (p. 611). The prevalence of ABPA is approximately 1–2% in asthma and 5–10% in CF. A variety of human leucocyte antigens (HLAs) convey both an increased and a decreased risk of developing the condition, suggesting that genetic susceptibility is important.

#### Clinical features

Clinical features depend on the stage of the disease. Common manifestations in the early phases include fever, breathlessness, cough productive of bronchial casts and worsening of asthmatic symptoms. The appearance of radiographic infiltrates may cause ABPA to be mistaken for pneumonia but the diagnosis may also be suggested by segmental or lobar collapse on chest X-rays of patients whose asthma symptoms are stable. Diagnostic features are shown in Box 17.58 and the typical Aspergillus hyphae in Figure 17.43. If bronchiectasis develops, the symptoms and complications of that disease often overshadow those of asthma.

#### Management

ABPA is generally considered an indication for regular therapy with low-dose oral glucocorticoids (prednisolone 7.5–10 mg daily) with the aim of suppressing the immunopathological responses and preventing progressive tissue damage. In some patients, itraconazole (400 mg/day) facilitates a reduction in oral glucocorticoids; a 4-month trial is usually recommended to assess its efficacy. The use of specific anti-IgE monoclonal antibodies is under consideration. Exacerbations, particularly when associated with new chest X-ray changes, should be treated promptly with prednisolone (40–60 mg daily) and physiotherapy. If persistent lobar collapse occurs, bronchoscopy (usually under general anaesthetic) should be performed to remove impacted mucus and ensure prompt re-inflation.

### Chronic pulmonary aspergillosis

The term chronic pulmonary aspergillosis (CPA) encompasses simple aspergilloma, chronic cavitory pulmonary aspergillosis, chronic fibrosing pulmonary aspergillosis, Aspergillus nodule and semi-invasive aspergillosis. They are uncommon conditions and challenging to diagnose and treat.

#### Simple aspergilloma

Cavities left by diseases such as TB or by damaged bronchi provide favourable conditions in which inhaled Aspergillus may lodge and germinate. At the earliest stage, CT scanning may identify an irregular mucosal wall and, as fungal growth progresses, this finally collapses into the cavity, forming a fungal ball that may be identified on imaging (Fig. 17.44).

Simple aspergillomas are often asymptomatic. They can, however, give rise to a variety of non-specific symptoms, such as lethargy and weight loss, and may cause recurrent haemoptysis, which may be life-threatening.
Infections of the respiratory system

Invasive pulmonary aspergillosis

Invasive pulmonary aspergillosis (IPA) is most commonly a complication of profound neutropenia caused by drugs (especially immunosuppressive agents) and/or disease (Box 17.59).

Clinical features

Acute IPA causes a severe necrotising pneumonia and must be considered in any immunocompromised patient who develops fever, new respiratory symptoms (particularly pleural pain or haemoptysis) or a pleural rub. Invasion of pulmonary vessels causes thrombosis and infarction, and systemic spread may occur.
to the brain, heart, kidneys and others organs. Tracheobronchial aspergillosis involvement is characterized by the formation of fungal plaques and ulceration.

HRCT characteristically shows macronodules (usually ≥1 cm), which may be surrounded by a ‘halo’ of intermediate attenuation if captured early (<5 days). Culture or histopathological evidence of Aspergillus in diseased tissues provides a definitive diagnosis but the majority of patients are too ill for invasive tests, such as bronchoscopy or lung biopsy. Other investigations include detection of Aspergillus cell-wall components (galactomannan and β-1,3-glucan) in blood or BAL fluid and Aspergillus DNA by PCR. Diagnosis is often inferred from a combination of features (Box 17.60).

### Management and prevention

IPA carries a high mortality rate, especially if treatment is delayed. The drug of choice is voriconazole. Second-line agents include liposomal amphotericin, caspofungin, posaconazole and isavuconazole. Response may be assessed clinically, radiologically and serologically (by estimation of the circulating galactomannan level). Recovery is dependent on immune reconstitution, which may be accompanied by enlargement and/or cavitation of pulmonary nodules.

Patients at risk of Aspergillus (and other fungal infections) should be managed in rooms with high-efficiency particulate air (HEPA) filters and laminar airflow. In areas with high spore counts, patients are advised to wear a mask if venturing outside their hospital room. Posaconazole (200 mg 3 times daily) or itraconazole (200 mg/day) may be prescribed for primary prophylaxis, and patients with a history of definite or probable IPA should be considered for secondary prophylaxis before further immunosuppression.

### Other fungal infections

Mucormycosis (p. 303) may present with a pulmonary syndrome that is clinically indistinguishable from acute IPA. Diagnosis relies on histopathology (where available) and/or culture of the organism from diseased tissue. The principles of treatment are as for other forms of mucormycosis: correction of predisposing factors, antifungal therapy with high-dose lipid amphotericin B or posaconazole (second line), and surgical débridement.

The endemic mycoses (histoplasmosis, coccidioidomycosis, blastomycosis and *Emergomyces* infection) and cryptococcosis are discussed on pages 302–304. *Pneumocystis jirovecii* pneumonia is described on page 318.

### Tumours of the bronchus and lung

Lung cancer is the most common cause of death from cancer worldwide, causing 1.59 million deaths per year (Box 17.61). Tobacco use is the major preventable cause. Just as tobacco use and cancer rates are falling in some developed countries, both smoking and lung cancer are rising in Eastern Europe and in many developing countries. The great majority of tumours in the lung are primary lung cancers and, in contrast to many other tumours, the prognosis remains poor, with fewer than 30% of patients surviving at 1 year and 6–8% at 5 years.

### 17.59 Risk factors for invasive aspergillosis

- Neutropenia: risk related to duration and degree
- Solid organ or allogeneic stem cell transplantation
- Prolonged high-dose glucocorticoid therapy
- Leukaemia and other haematological malignancies
- Cytotoxic chemotherapy
- Advanced HIV disease
- Severe chronic obstructive pulmonary disease
- Critically ill patients on intensive care units
- Chronic granulomatous disease

### 17.60 Criteria for the diagnosis of probable invasive pulmonary aspergillosis

#### Host factors

- Recent history of neutropenia (<0.5×10^9/L for ≥10 days) temporally related to the onset of fungal disease
- Recipient of allogeneic stem cell transplant
- Prolonged use of glucocorticoids (average minimum 0.3 mg/kg/day prednisolone or equivalent) for >3 weeks (excludes allergic bronchopulmonary aspergillosis)
- Treatment with other recognised T-cell immune suppressants, such as ciclosporin, tumour necrosis factor, alpha-blockers, specific monoclonal antibodies (e.g. alemtuzumab) or nucleoside analogues during the last 90 days
- Inherited severe immune deficiency, e.g. chronic granulomatous disease or severe combined immune deficiency (p. 79)

#### Clinical criteria

- The presence of one of the following on CT:
  - Dense, well-circumscribed lesion(s) with or without a halo sign
  - Air crescent sign
  - Cavity

#### Tracheobronchitis

- Tracheobronchial ulceration, nodule, pseudomembrane, plaque or eschar seen on bronchoscopy

#### Mycological criteria

- Mould in sputum, BAL fluid or bronchial brush, indicated by one of the following:
  - Recovery of fungal elements indicating a mould of *Aspergillus*
  - Recovery by culture of a mould of *Aspergillus*
  - β-1,3-glucan detected in serum (detects other species of fungi, as well as *Aspergillus*)

1Must be consistent with the mycological findings and temporally related to current episode. *May be useful as a preliminary screening tool for invasive aspergillosis.

(BAL = bronchoalveolar lavage)

In women, smoking prevalence and deaths from lung cancer continue to increase, and more women now die of lung cancer than breast cancer in the USA and the UK.

Pathology
Lung cancers arise from the bronchial epithelium or mucous glands. The common cell types are listed in Box 17.62. When the tumour occurs in a large bronchus, symptoms arise early but tumours originating in a peripheral bronchus can grow very large without producing symptoms, resulting in delayed diagnosis. Peripheral squamous tumours may undergo central necrosis and cavitation and may resemble a lung abscess on X-ray (Fig. 17.47). Lung cancer may involve the pleura directly or by lymphatic spread and may extend into the chest wall, invading the intercostal nerves or the brachial plexus and causing pain. Lymphatic spread to mediastinal and supraclavicular lymph nodes often occurs before diagnosis. Blood-borne metastases occur most commonly in liver, bone, brain, adrenals and skin. Even a small primary tumour may cause widespread metastatic deposits and this is a particular characteristic of small-cell lung cancers.

Clinical features
Lung cancer presents in many different ways, reflecting local, metastatic or paraneoplastic tumour effects.

Cough
This is the most common early symptom. It is often dry but secondary infection may cause purulent sputum. A change in the character of a smoker’s cough, particularly if associated with other new symptoms, should always raise suspicion of lung cancer.

Haemoptysis
Haemoptysis is common, especially with central bronchial tumours. Although it may be caused by bronchitic...
Breathlessness may be caused by collapse or pneumonia, or by tumour causing a large pleural effusion or compressing a phrenic nerve and leading to diaphragmatic paralysis.

Pain and nerve entrapment Pleural pain may indicate malignant pleural invasion, although it can occur with distal infection. Intercostal nerve involvement causes pain in the distribution of a thoracic dermatome. Cancer in the lung apex may cause Horner’s syndrome (ipsilateral partial ptosis, enophthalmos, miosis and hypohidrosis of the face; p. 1091) due to involvement of the sympathetic nerves to the eye at or above the stellate ganglion. Pancoast’s syndrome (pain in the inner aspect of the arm, sometimes with small muscle wasting in the hand) indicates malignant destruction of the T1 and C8 roots in the lower part of the brachial plexus by an apical lung tumour.

Mediastinal spread Involvement of the oesophagus may cause dysphagia. If the pericardium is invaded, arrhythmia or pericardial effusion may occur. Superior vena cava obstruction by malignant nodes causes suffusion and swelling of the neck and face, conjunctival oedema, headache and dilated veins on the chest wall and is most commonly due to lung cancer. Involvement of the left recurrent laryngeal nerve by tumours at the left hilum causes vocal cord paralysis, voice alteration and a ‘bovine’ cough (lacking the normal explosive character). Supraclavicular lymph nodes may be palpably enlarged or identified using ultrasound; if so, a needle aspirate may provide a simple means of cytological diagnosis.

Metastatic spread This may lead to focal neurological defects, epileptic seizures, personality change, jaundice, bone pain or skin nodules. Lassitude, anorexia and weight loss usually indicate metastatic spread.

Finger clubbing Overgrowth of the soft tissue of the terminal phalanx, leading to increased nail curvature and nail bed fluctuation, is often seen (p. 546).

Hypertrophic pulmonary osteoarthropathy (HPOA) This is a painful periostitis of the distal tibia, fibula, radius and ulna, with local tenderness and sometimes pitting oedema over the anterior shin. X-rays reveal subperiosteal new bone formation. While

---

**Fig. 17.48 Collapse of the right lung: effects on neighbouring structures.**

A Chest X-ray. B The typical abnormalities are highlighted.

---

### 17.63 Causes of large bronchus obstruction

**Common**
- Lung cancer or adenoma
- Enlarged tracheobronchial lymph nodes (malignant or tuberculous)
- Inhaled foreign bodies (especially right lung)
- Bronchial casts or plugs consisting of inspissated mucus or blood clot (especially asthma, cystic fibrosis, haemoptysis, debility)
- Collections of mucus or mucopus retained in the bronchi as a result of ineffective expectoration (especially postoperative following abdominal surgery)

**Rare**
- Aortic aneurysm
- Giant left atrium
- Pericardial effusion
- Congenital bronchial atresia
- Fibrous bronchial stricture (e.g. following tuberculosis or bronchial surgery/lung transplant)

---

**Breathlessness** Breathlessness may be caused by collapse or pneumonia, or by tumour causing a large pleural effusion or compressing a phrenic nerve and leading to diaphragmatic paralysis.

**Pain and nerve entrapment** Pleural pain may indicate malignant pleural invasion, although it can occur with distal infection. Intercostal nerve involvement causes pain in the distribution of a thoracic dermatome. Cancer in the lung apex may cause Horner’s syndrome (ipsilateral partial ptosis, enophthalmos, miosis and hypohidrosis of the face; p. 1091) due to involvement of the sympathetic nerves to the eye at or above the stellate ganglion. Pancoast’s syndrome (pain in the inner aspect of the arm, sometimes with small muscle wasting in the hand) indicates malignant destruction of the T1 and C8 roots in the lower part of the brachial plexus by an apical lung tumour.
Tumours of the bronchus and lung

Invasive investigation, sputum cytology may reveal malignant cells, although the yield is low. In patients with pleural effusions, pleural aspiration and biopsy is the preferred investigation. Where facilities exist, thoracoscopy increases yield by allowing targeted biopsies under direct vision.

In patients with metastatic disease, the diagnosis can often be confirmed by needle aspiration or biopsy of affected lymph nodes, skin lesions, liver or bone marrow.

Non-metastatic extrapulmonary effects (Box 17.64) The syndrome of inappropriate antidiuretic hormone secretion (SIADH, p. 357) and ectopic adrenocorticotrophic hormone secretion (p. 670) are usually associated with small-cell lung cancer. Hypercalcaemia may indicate malignant bone destruction or production of hormone-like peptides by a tumour. Associated neurological syndromes may occur with any type of lung cancer.

Investigations

The main aims of investigation are to confirm the diagnosis, establish the histological cell type and define the extent of the disease.

Imaging

Lung cancer produces a range of appearances on chest X-ray, from lobar collapse (see Fig. 17.5, p. 552) to mass lesions, effusion or malignant rib destruction (Fig. 17.49). CT should be performed early, as it may reveal mediastinal or metastatic spread and is helpful for planning biopsy procedures, e.g. in establishing whether a tumour is accessible by bronchoscopy or percutaneous CT-guided biopsy.

Biopsy and histopathology

Over half of primary lung tumours can be visualised and sampled directly by biopsy and brushing using a flexible bronchoscope. Bronchoscopy also allows an assessment of operability, from the proximity of central tumours to the main carina (Fig. 17.50).

For tumours that are too peripheral to be accessible by bronchoscope, the yield of “blind” bronchoscopic washings and brushings from the radiologically affected area is low and percutaneous needle biopsy under CT or ultrasound guidance is a more reliable way to obtain a histological diagnosis. There is a small risk of iatrogenic pneumothorax, which may preclude the procedure if there is extensive coexisting COPD. In patients with a peripheral tumour and enlarged hilar or paratracheal lymph nodes on CT, bronchoscopy with EBUS-guided node sampling may allow both diagnosis and staging. In those who are unfit for invasive investigation, sputum cytology may reveal malignant cells, although the yield is low.

In patients with pleural effusions, pleural aspiration and biopsy is the preferred investigation. Where facilities exist, thoracoscopy increases yield by allowing targeted biopsies under direct vision. In patients with metastatic disease, the diagnosis can often be confirmed by needle aspiration or biopsy of affected lymph nodes, skin lesions, liver or bone marrow.
Staging to guide treatment

The propensity of small-cell lung cancer to metastasise early means these patients are usually not suitable for surgical intervention. In non-small-cell lung cancer (NSCLC), treatment and prognosis are determined by disease extent, so careful staging is required. CT is used early to detect obvious local or distant spread. Enlarged upper mediastinal nodes may be sampled using an EBUS-equipped bronchoscope or by mediastinoscopy. Nodes in the lower mediastinum can be sampled through the oesophageal wall using endoscopic ultrasound. Combined CT and whole-body PET (see Fig. 17.6, p. 553) is commonly used to detect occult but metabolically active metastases. Head CT, radionuclide bone scanning, liver ultrasound and bone marrow biopsy are generally reserved for patients with clinical, haematological or biochemical evidence of tumour spread to these sites. Information on tumour size and nodal and metastatic spread is then collated to assign the patient to one of seven staging groups that determine optimal management and prognosis (Fig. 17.51). Detailed physiological testing is required to assess whether respiratory and cardiac function is sufficient to allow aggressive treatment.

Management

Surgical resection carries the best hope of long-term survival but some patients treated with radical radiotherapy and chemotherapy also achieve prolonged remission or cure. In over 75% of cases, treatment with the aim of cure is not possible or is inappropriate due to extensive spread or comorbidity. Such patients are offered palliative therapy and best supportive care. Radiotherapy and, in some cases, chemotherapy can relieve symptoms.

Surgical treatment

Accurate pre-operative staging, coupled with improvements in surgical and post-operative care, now offers 5-year survival rates of over 75% in stage I disease (N0, tumour confined within visceral pleura) and 55% in stage II disease, which includes resection in patients with ipsilateral peribronchial or hilar node involvement.

Radiotherapy

While much less effective than surgery, radical radiotherapy can offer long-term survival in selected patients with localised disease in whom comorbidity precludes surgery. Radical radiotherapy is usually combined with chemotherapy when lymph nodes are involved (stage III). Highly targeted (stereotactic) radiotherapy may be given in 3–5 treatments for small lesions.

The greatest value of radiotherapy, however, is in the palliation of distressing complications, such as superior vena cava obstruction, recurrent haemoptysis, and pain caused by chest wall invasion or by skeletal metastatic deposits. Obstruction of the trachea and main bronchi can also be relieved temporarily. Radiotherapy can be used in conjunction with chemotherapy in the treatment of small-cell carcinoma and is particularly efficient at preventing the development of brain metastases in patients who have had a complete response to chemotherapy (p. 1331).

Chemotherapy

The treatment of small-cell carcinoma with combinations of cytotoxic drugs, sometimes with radiotherapy, can increase median survival from 3 months to well over a year. The use of combinations of chemotherapeutic drugs requires considerable skill and should be overseen by multidisciplinary teams of clinical oncologists and specialist nurses. Combination chemotherapy leads to better outcomes than single-agent treatment. Regular cycles of therapy, including combinations of intravenous cyclophosphamide, doxorubicin and vincristine or intravenous cisplatin and etoposide, are commonly used.

In NSCLC chemotherapy is less effective, though platinum-based chemotherapy regimens offer 30% response rates and a modest increase in survival, and are widely used. Some non-small-cell lung tumours, particularly adenocarcinomas in non-smokers, carry detectable mutations, e.g. in the epidermal growth factor receptor (EGFR) gene. Tyrosine kinase inhibitors, such as erlotinib and monoclonal antibodies to EGFR (e.g. bevacizumab), show improved treatment responses in metastatic

---

**Tumour stage and 5-year survival in non-small-cell lung cancer.** The figure shows the relationship between tumour extent (size, lymph node status and metastases) and prognosis (% survival at 5 years for each clinical stage). Based on data from Detterbeck FC, Boffa DJ, Kim AW, Tanoue T. The eighth edition lung cancer stage classification. Chest 2017; 151:193–203.
NSCLC and EGFR mutations, and similar approaches are being developed to target other known genetic abnormalities.

In NSCLC there is some evidence that chemotherapy given before surgery may increase survival and can effectively ‘down-stage’ disease with limited nodal spread. Post-operative chemotherapy is now proven to enhance survival rates when operative samples show nodal involvement by tumour.

Nausea and vomiting are common side-effects of chemotherapy and are best treated with 5-HT\textsubscript{3} receptor antagonists (p. 1353).

Laser therapy and stenting

Palliation of symptoms caused by major airway obstruction can be achieved in selected patients using bronchoscopic laser treatment to clear tumour tissue and allow re-aeration of collapsed lung. The best results are achieved in tumours of the main bronchi. Endobronchial stents can be used to maintain airway patency in the face of extrinsic compression by malignant nodes.

General aspects of management

The best outcomes are obtained when lung cancer is managed in specialist centres by multidisciplinary teams, including oncologists, thoracic surgeons, respiratory physicians and specialist nurses. Effective communication, pain relief and attention to diet are important. Lung tumours can cause clinically significant depression and anxiety, and these may need specific therapy. The management of non-metastatic endocrine manifestations is described in Chapter 18. When a malignant pleural effusion is present, an attempt should be made to drain the pleural cavity using an intercostal drain; provided that the lung fully re-expands, pleurodesis with a sclerosing agent, such as talc, should be performed to prevent recurrent effusion.

Prognosis

The overall prognosis in lung cancer is very poor, 70% of patients dying within a year of diagnosis and only 6–8% surviving 5 years after diagnosis. The best prognosis is with well-differentiated squamous cell tumours that have not metastasised and are amenable to surgical resection. The clinical features and prognosis of some less common tumours are given in Box 17.65.

Secondary tumours of the lung

Blood-borne metastatic deposits in the lungs may be derived from many primary carcinomas, in particular breast, kidney, uterus, ovary, testes and thyroid, and also from osteogenic and other sarcomas. These secondary deposits are usually multiple and bilateral. Often there are no respiratory symptoms and the diagnosis is incidental on X-ray. Breathlessness may occur if a considerable amount of lung tissue has been replaced by metastatic tumour. Endobronchial deposits are uncommon but can cause haemoptysis and lobar collapse.

Lymphatic infiltration may develop in carcinoma of the breast, stomach, bowel, pancreas or bronchus. ‘Lymphangitic carcinomatosis’ causes severe, rapidly progressive breathlessness with marked hypoxaemia. The chest X-ray shows diffuse pulmonary shadowing radiating from the hilar regions, often with septal lines, and CT shows characteristic polygonal thickened interlobular septa. Palliation of breathlessness with opiates may help (p. 1353).

### Tumours of the mediastinum

Figure 17.52 shows the major compartments of the mediastinum and Box 17.66 lists likely causes of a mediastinal mass.

#### 17.66 Causes of a mediastinal mass

**Superior mediastinum**
- Retrosternal goitre
- Persistent left superior vena cava
- Prominent left subclavian artery
- Thymic tumour
- Dermoid cyst
- Lymphoma
- Aortic aneurysm
- Germ cell tumour
- Pericardial cyst
- Hiatus hernia through the diaphragmatic foramen of Morgagni

**Anterior mediastinum**
- Neurogenic tumour
- Paravertebral abscess
- Oesophageal lesion
- Aortic aneurysm
- Foregut duplication

**Posterior mediastinum**
- Dermoid cyst
- Thymic tumour
- Lymphoma
- Sarcoidosis
- Aortic aneurysm
- Hiatus hernia

**Middle mediastinum**
- Lung cancer
- Lymphoma
- Bronchogenic cyst
- Thymic tumour

17
A benign mediastinal tumour generally appears on chest X-ray as a sharply circumscribed mediastinal opacity encroaching on one or both lung fields (Fig. 17.53). CT (or MRI) is the investigation of choice for mediastinal tumours (e.g. see Fig. 18.12, p. 648).

A malignant mediastinal tumour seldom has a clearly defined margin and often presents as a general broadening of the mediastinum.

Bronchoscopy may reveal a primary lung cancer causing mediastinal lymphadenopathy. EBUS may be used to guide sampling of peribronchial masses. The posterior mediastinum can be imaged and biopsied via the oesophagus using endoscopic ultrasound (p. 553).

Mediastinoscopy under general anaesthetic can be used to visualise and biopsy masses in the superior and anterior mediastinum but surgical exploration of the chest, with removal of part or all of the tumour, is often required to obtain a histological diagnosis.
Interstitial and infiltrative pulmonary diseases

Diffuse parenchymal lung disease

The diffuse parenchymal lung diseases (DPLDs) are a heterogeneous group of conditions affecting the pulmonary parenchyma (interstitium) and/or alveolar lumen, which are frequently considered collectively as they share a sufficient number of clinical physiological and radiographic similarities (Box 17.68).

Clinical presentation
- Cough: usually dry, persistent and distressing
- Breathlessness: usually slowly progressive; insidious onset; acute in some cases

Examination findings
- Crackles: typically bilateral and basal
- Clubbing: common in idiopathic pulmonary fibrosis but also seen in other types, e.g. asbestosis
- Central cyanosis and signs of right heart failure in advanced disease

Radiology
- Chest X-ray: typically small lung volumes with reticulonodular shadowing but may be normal in early or limited disease
- High-resolution computed tomography: combinations of ground glass changes, reticulonodular shadowing, honeycomb cysts and traction bronchiectasis, depending on stage of disease

Pulmonary function
- Typically restrictive ventilatory defect with reduced lung volumes and impaired gas transfer; exercise tests assess exercise tolerance and exercise-related fall in $\text{SaO}_2$

Management
Benign mediastinal tumours should be removed surgically because most produce symptoms sooner or later. Cysts may become infected, while neural tumours have the potential to undergo malignant transformation. The operative mortality is low in the absence of coexisting cardiovascular disease, COPD or extreme age.

Idiopathic interstitial pneumonias

The idiopathic interstitial pneumonias represent a major subgroup of DPLD that are grouped together as a result of their unknown aetiology (Box 17.70). They are often distinguished by the predominant histological pattern on tissue biopsy; hence they are frequently referred to by their pathological description, e.g. usual interstitial pneumonia (UIP) or non-specific interstitial pneumonia (NSIP). The most important of these is idiopathic pulmonary fibrosis.

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis is defined as a progressive fibrosing interstitial pneumonia of unknown cause, occurring in adults and associated with the histological or radiological pattern of UIP. Important differentials include fibrosing diseases caused by infection, malignancy, pulmonary oedema, and aspiration pneumonitis.
CT scanning it may present as an incidental finding in an otherwise asymptomatic individual but more typically presents with progressive breathlessness (which may have been insidious) and a non-productive cough. Constitutional symptoms are unusual. Clinical findings include finger clubbing and the presence of bi-basal fine late inspiratory crackles likened to the unfastening of Velcro.

Investigations

These are summarised in Box 17.71. Established IPF will be apparent on chest X-ray as a bilateral lower lobe and subpleural reticular shadowing. The chest X-ray may be normal in individuals with early or limited disease, however. HRCT typically demonstrates a patchy, predominantly peripheral, subpleural and basal reticular pattern and, in more advanced disease, the presence of honeycombing cysts and traction bronchiectasis by occupational exposure, medication or connective tissue diseases, which must be excluded by careful history, examination and investigation.

The histological features of the condition are suggestive of repeated episodes of focal damage to the alveolar epithelium consistent with an autoimmune process but the aetiology remains elusive: speculation has included exposure to viruses (e.g. Epstein–Barr virus), occupational dusts (metal or wood), drugs (antidepressants) or chronic gastro-oesophageal reflux. Familial cases are rare but genetic factors that control the inflammatory and fibrotic response are likely to be important. There is a strong association with cigarette smoking.

Clinical features

IPF usually presents in the older adult and is uncommon before the age of 50 years. With the advent of widespread idiopathic interstitial pneumonias

</tbody>
</table>
Management

The management options for IPF are improving. If the vital capacity is between 50% and 80% predicted, patients may be offered either pirfenidone (an antifibrotic agent) or nintedanib (a tyrosine kinase inhibitor). Both of these agents have been shown to reduce the rate of decline in lung function. Patients taking pirfenidone should be advised to avoid direct exposure to sunlight and use photoprotective clothing and high-protection sunscreens. Nintedanib may be accompanied by diarrhoea.

Neither drug improves cough or breathlessness and treatment should be discontinued if lung function declines by more than 10% over the first year of treatment. Medication to control gastro-oesophageal reflux may improve the cough. Current smokers should be apprised of the increased risk of lung cancer and advised to stop. Influenza and pneumococcal vaccination should be recommended. Patients should be encouraged to exercise and participate in pulmonary rehabilitation using ambulatory oxygen if appropriate. Domiciliary oxygen should be considered for palliation of breathlessness in severe cases. Where appropriate, lung transplantation should be considered. The optimum treatment for acute exacerbations is unknown. Treatment is largely supportive. Broad-spectrum antibiotics may be required.
Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology that is characterised by the presence of non-caseating granulomas (Fig. 17.58). The condition is more frequently described in colder parts of northern Europe. It also appears to be more common and more severe in those from a West Indian or Asian background; Eskimos, Arabs and Chinese are rarely affected. The tendency for sarcoid to present in the spring and summer has led to speculation about the role of infective agents, including mycobacteria, propionibacteria and viruses, but the cause remains elusive. Genetic susceptibility is supported by familial clustering; a range of class II HLA alleles confer protection from, or susceptibility to, the condition. Sarcoidosis occurs less frequently in smokers. It may be associated with common variable immunodeficiency (p. 79).

Clinical features
Sarcoidosis is considered with other DPLDs, as over 90% of cases affect the lungs, but the condition can involve almost any organ (Fig. 17.59 and Box 17.72). Löfgren’s syndrome – an acute illness characterised by erythema nodosum, peripheral arthropathy, uveitis, bilateral hilar lymphadenopathy (BHL), lethargy and occasionally fever – is often seen in young women. Alternatively, BHL may be detected in an otherwise asymptomatic individual undergoing a chest X-ray for other purposes. Pulmonary disease may also present in a more insidious manner with cough, exertional breathlessness and radiographic infiltrates; chest auscultation is often surprisingly unremarkable. Fibrosis

Prognosis
The natural history is usually one of steady decline; however, some patients are prone to exacerbations accompanied by an acute deterioration in breathlessness, disturbed gas exchange, and new ground glass changes or consolidation on HRCT. In advanced disease, central cyanosis is detectable and patients may develop pulmonary hypertension and features of right heart failure. A median survival of 3 years is widely quoted; the rate of disease progression varies considerably, however, from death within a few months to survival with minimal symptoms for many years. Serial lung function testing may provide useful prognostic information, relative preservation of lung function suggesting longer survival and significantly impaired gas transfer and/or desaturation on exercise heralding a poorer prognosis. The finding of high numbers of fibroblastic foci on biopsy suggests a more rapid deterioration.

Non-specific interstitial pneumonia
The clinical picture of fibrotic NSIP is similar to that of IPF, although patients tend to be women and younger in age. As with UIP, the condition may present as an isolated idiopathic pulmonary condition, but an NSIP pattern is often associated with connective tissue disease, certain drugs, chronic hypersensitivity pneumonitis or HIV infection and care must be taken to exclude these possibilities. As with UIP, the pulmonary condition may precede the appearance of connective tissue disease. HRCT findings are less specific than with IPF and lung biopsy may be required. The prognosis is significantly better than that of IPF, particularly in the cellular form of the condition, and the 5-year mortality rate is typically less than 15%.
Interstitial and infiltrative pulmonary diseases

• May provide a non-specific marker of disease activity and can assist in monitoring the clinical course. Chest radiography has been used to stage sarcoid (Box 17.73). In patients with pulmonary infiltrates, pulmonary function testing may show a restrictive defect accompanied by impaired gas exchange. Exercise tests may provide a non-specific marker of disease activity and can assist in monitoring the clinical course. Chest radiography has been used to stage sarcoid (Box 17.73). In patients with pulmonary infiltrates, pulmonary function testing may show a restrictive defect accompanied by impaired gas exchange. Exercise tests

**Interpretation of X-ray changes in sarcoidosis**

- **Stage I:** BHL (usually symmetrical); paratracheal nodes often enlarged
  - Often asymptomatic but may be associated with erythema nodosum and arthralgia. The majority of cases resolve spontaneously within 1 year

- **Stage II:** BHL and parenchymal infiltrates
  - Patients may present with breathlessness or cough. The majority of cases resolve spontaneously

- **Stage III:** parenchymal infiltrates without BHL
  - Disease less likely to resolve spontaneously

- **Stage IV:** pulmonary fibrosis
  - Can cause progression to ventilatory failure, pulmonary hypertension and cor pulmonale

(BHL = bilateral hilar lymphadenopathy)

**Investigations**

Lymphopenia is characteristic and liver function tests may be mildly deranged. Hypercalcaemia may be present (reflecting increased formation of calcitriol – 1,25-dihydroxyvitamin D – by alveolar macrophages), particularly if the patient has been exposed to strong sunlight. Hypercalciuria may also be seen and may lead to nephrocalcinosis. Serum angiotensin-converting enzyme (ACE) occurs in around 20% of cases of pulmonary sarcoidosis and may cause a silent loss of lung function. Pleural disease is uncommon and finger clubbing is not a feature. Complications such as bronchiectasis, aspergillosis, pneumothorax, pulmonary hypertension and cor pulmonale have been reported but are rare.

**Presentation of sarcoidosis**

- Asymptomatic: abnormal routine chest X-ray (~30%) or abnormal liver function tests
- Respiratory and constitutional symptoms (20–30%)
- Erythema nodosum and arthralgia (20–30%)
- Ocular symptoms (5–10%)
- Skin sarcoid (including lupus pernio) (5%)
- Supraclavicular lymphadenopathy (5%)
- Other (1%), e.g. hypercalcaemia, diabetes insipidus, cranial nerve palsies, cardiac arrhythmias, nephrocalcinosis

**Chest X-ray changes in sarcoidosis**

- **Stage I:** BHL (usually symmetrical); paratracheal nodes often enlarged
  - Often asymptomatic but may be associated with erythema nodosum and arthralgia. The majority of cases resolve spontaneously within 1 year

- **Stage II:** BHL and parenchymal infiltrates
  - Patients may present with breathlessness or cough. The majority of cases resolve spontaneously

- **Stage III:** parenchymal infiltrates without BHL
  - Disease less likely to resolve spontaneously

- **Stage IV:** pulmonary fibrosis
  - Can cause progression to ventilatory failure, pulmonary hypertension and cor pulmonale

(BHL = bilateral hilar lymphadenopathy)
may reveal oxygen desaturation. Bronchoscopy may demonstrate a ‘cobblestone’ appearance of the mucosa, and bronchial and transbronchial biopsies usually show non-caseating granulomas, as may samples from the mediastinal nodes obtained by EBUS. Bronchoalveolar lavage fluid typically contains an increased CD4:CD8 T-cell ratio. Characteristic HRCT appearances include reticulonodular opacities that follow a perilymphatic distribution centred on bronchovascular bundles and the subpleural areas. PET scanning can detect extrapulmonary disease.

The occurrence of erythema nodosum with BHL on chest X-ray is often sufficient for a confident diagnosis, without recourse to a tissue biopsy. Similarly, a typical presentation with classical HRCT features may also be accepted. In other instances, however, the diagnosis should be confirmed by histological examination of the involved organ. The presence of anergy (e.g. to tuberculin skin tests) may support the diagnosis.

**Management**

Patients who present with acute illness and erythema nodosum should receive NSAIDs and, on occasion, a short course of glucocorticoids. The majority of patients enjoy spontaneous remission and so, if there is no evidence of organ damage, systemic glucocorticoid therapy can be withheld for 6 months. However, prednisolone (at a starting dose of 20–40 mg/day) should be commenced immediately in the presence of hypercalcaemia, pulmonary impairment, renal impairment and uveitis. Topical glucocorticoids may be useful in cases of mild uveitis, and inhaled glucocorticoids have been used to shorten the duration of systemic glucocorticoid use in asymptomatic parenchymal sarcoid. Patients should be warned that strong sunlight may precipitate hypercalcaemia and endanger renal function.

Features suggesting a less favourable outlook include age over 40, Afro-Caribbean ethnicity, persistent symptoms for more than 6 months, the involvement of more than three organs, lupus pernio (see Fig. 17.59) and a stage III/IV chest X-ray. In patients with severe disease, methotrexate (10–20 mg/week), azathioprine (50–150 mg/day) and specific tumour necrosis factor alpha (TNF-α) inhibitors (p. 1006) have been effective. Chloroquine, hydroxychloroquine and low-dose thalidomide may be useful in cutaneous sarcoid with limited pulmonary involvement. Selected patients may be referred for consideration of single lung transplantation. The overall mortality is low (1–5%) and usually reflects cardiac involvement or pulmonary fibrosis.

---

**Lung diseases due to systemic inflammatory disease**

---

### The acute respiratory distress syndrome

See page 198.

### Respiratory involvement in connective tissue disorders

Pulmonary complications of connective tissue disease are common, affecting the airways, alveoli, pulmonary vasculature, diaphragm and chest wall muscles, and the chest wall itself. In some instances, pulmonary disease may precede the appearance of the connective tissue disorder (Box 17.74). Indirect associations between connective tissue disorders and respiratory complications include those due to disease in other organs, e.g. thrombocytopenia causing haemoptysis; pulmonary toxic effects of drugs used to treat the connective tissue disorder (e.g. gold and methotrexate); and secondary infection due to the disease itself, neutropenia or immunosuppressive drug regimens.

**Rheumatoid disease**

Pulmonary involvement in rheumatoid disease is important, accounting for around 10–20% of the mortality associated with the condition (p. 1021). The majority of cases occur within 5 years of the rheumatological diagnosis but pulmonary manifestations may precede joint involvement in 10–20%. Pulmonary fibrosis is the most common pulmonary manifestation. All forms of interstitial disease have been described but NSIP is probably the most common. A rare variant of localised upper lobe fibrosis and cavitation is occasionally seen.

Pleural effusion is common, especially in men with seropositive disease. Effusions are usually small and unilateral, but can be large and bilateral. Most resolve spontaneously. Biochemical testing shows an exudate with markedly reduced glucose levels and raised lactate dehydrogenase (LDH). Effusions that fail to resolve spontaneously may respond to a short course of oral prednisolone (30–40 mg daily) but some become chronic.

Rheumatoid pulmonary nodules are usually asymptomatic and detected incidentally on imaging. They are most often multiple and subpleural in site (Fig. 17.60). Solitary nodules can mimic primary lung cancer; when multiple, the differential...
interstitial and infiltrative pulmonary diseases • 611

Pulmonary eosinophilia and vasculitides

Pulmonary eosinophilia refers to the association of radiographic (usually pneumonic) abnormalities and peripheral blood eosinophilia. The term encompasses a group of disorders of different aetiology (Box 17.75). Eosinophils are the predominant cell recovered in sputum or BAL, and eosinophil products are likely to prime mediators of tissue damage.

Acute eosinophilic pneumonia

Acute eosinophilic pneumonia is an acute febrile illness (of less than 5 days’ duration), characterised by diffuse pulmonary infiltrates and hypoxic respiratory failure. The pathology is usually that of diffuse alveolar damage. Diagnosis is confirmed by BAL, which characteristically demonstrates >25% eosinophils. The condition is usually idiopathic but drug reactions should be considered. Glucocorticoids invariably induce prompt and complete resolution.

Chronic eosinophilic pneumonia

Chronic eosinophilic pneumonia typically presents in an insidious manner with malaise, fever, weight loss, breathlessness and unproductive cough. It is more common in middle-aged females. The classical chest X-ray appearance has been likened to the photographic negative of pulmonary oedema with bilateral, peripheral and predominantly upper lobe parenchymal shadowing. The peripheral blood eosinophil count is almost always very high, and the erythrocyte sedimentation rate (ESR) and total serum IgE are elevated. BAL reveals a high proportion of eosinophils.

Box 17.75 Pulmonary eosinophilia

Extrinsic (cause known)

- Helminths: e.g. Ascaris, Toxocara, Filaria
- Drugs: nitrofurantoin, para-aminosalicylic acid (PAS), sulfasalazine, imipramine, chlorpropamide, phenylbutazone
- Fungi: e.g. Aspergillus fumigatus causing allergic bronchopulmonary aspergillosis (p. 596)

Intrinsic (cause unknown)

- Cryptogenic eosinophilic pneumonia
- Eosinophilic granulomatosis with polyangiitis (formerly Churg–Strauss syndrome), diagnosed on the basis of four or more of the following features:
  - Asthma
  - Peripheral blood eosinophilia >1.5×10^9/L (or >10% of a total white cell count)
  - Mononeuropathy or polyneuropathy
  - Pulmonary infiltrates
  - Paranasal sinus disease
  - Eosinophilic vasculitis on biopsy of an affected site
- Hypereosinophilic syndrome
- Polyarteritis nodosa (p. 1042; rare)
in the lavage fluid. Response to prednisolone (20–40 mg daily) is usually dramatic. Prednisolone can usually be withdrawn after a few weeks without relapse but long-term, low-dose therapy is occasionally necessary.

### Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia occurs as a result of a mosquito-borne filarial infection with Wuchereria bancrofti or Brugia malayi (p. 290). The condition presents with fever, weight loss, dyspnoea and asthma-like symptoms. The peripheral blood eosinophilia is marked, as is the elevation of total IgE. High antifilarial antibody titres are seen. The diagnosis may be confirmed by a response to treatment with diethylcarbamazine (6 mg/kg/day for 3 weeks). Tropical pulmonary eosinophilia must be distinguished from infection with Strongyloides stercoralis (p. 289) as, in strongyloidiasis, glucocorticoids may cause a life-threatening reaction.

### Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (formerly referred to as Wegener’s granulomatosis) is a rare vasculitic and granulomatous condition (p. 1041). The lung is commonly involved in systemic forms of the disease but a limited pulmonary form may also occur. Respiratory symptoms include cough, haemoptysis and chest pain. Associated upper respiratory tract manifestations include nasal discharge and crusting, and otitis media. Fever, weight loss and anaemia are common. Radiological features include multiple nodules and cavitation that may resemble primary or metastatic carcinoma, or a pulmonary abscess. Tissue biopsy confirms the distinctive pattern of necrotising granulomas and necrotising vasculitis. Other respiratory complications include tracheal subglottic stenosis and saddle nose deformity. The differential diagnoses include mycobacterial and fungal infection and other forms of pulmonary vasculitis, including polyarteritis nodosa (pulmonary infarction), microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis, and Wegener’s granulomatosis. Granulomas may occur in response to infection with Strongyloides stercoralis (p. 289), but eosinophilia and association with asthma, necrotising sarcoid, bronchocentric granulomatosis and lymphomatoid granulomatosis.

### Goodpasture’s disease

This describes the association of pulmonary haemorrhage and glomerulonephritis, in which IgG antibodies bind to the glomerular or alveolar basement membranes (p. 401). Pulmonary disease usually precedes renal involvement and includes radiographic infiltrates and hypoxia with or without haemoptysis. It occurs more commonly in men and almost exclusively in smokers.

### Lung diseases due to irradiation and drugs

#### Radiotherapy

Targeting radiotherapy to certain tumours is inevitably accompanied by irradiation of normal lung tissue. Although delivered in divided doses, the effects are cumulative. Acute radiation pneumonitis is typically seen within 6–12 weeks and presents with cough and dyspnoea. This may resolve spontaneously but responds to glucocorticoid treatment. Chronic interstitial fibrosis may present several months later with symptoms of exertional dyspnoea and cough. Changes are often confined to the area irradiated but may be bilateral. Established post-irradiation fibrosis does not usually respond to glucocorticoid treatment. The pulmonary effects of radiation (p. 1332) are exacerbated by treatment with cytotoxic drugs, and the phenomenon of ‘recall pneumonitis’ describes the appearance of radiation injury in a previously irradiated area when chemotherapy follows radiotherapy. If the patient survives, there are long-term risks of lung cancer.

### Drugs

Drugs may cause a variety of pulmonary conditions (Box 17.76). Pulmonary fibrosis may occur in response to a variety of drugs but is seen most frequently with bleomycin, methotrexate, amiodarone and nitrofurantoin. Eosinophilic pulmonary reactions can also be caused by drugs. The pathogenesis may be an immune reaction similar to that in hypersensitivity pneumonitis, which specifically attracts large numbers of eosinophils into the lungs. This type of reaction is well described as a rare reaction to a variety of antineoplastic agents (e.g. bleomycin), antibiotics (e.g. sulphonamides), sulfasalazine and the anticonvulsants phenytoin and carbamazepine. Patients usually present with breathlessness, cough and fever. The chest x-ray characteristically shows patchy shadowing. Most cases resolve completely on withdrawal of the drug, but if the reaction is severe, rapid resolution can be obtained with glucocorticoids.

Drugs may also cause other lung diseases, such as asthma, pulmonary haemorrhage, pleural effusion and, rarely, pleural thickening. An ARDS-like syndrome of acute non-cardiogenic pulmonary oedema may present with dramatic onset of breathlessness, severe hypoxaemia and signs of alveolar oedema.

on the chest X-ray. This syndrome has been reported most frequently in cases of opiate overdose in drug addicts (p. 142) but also after salicylate overdose, and there are occasional reports of its occurrence after therapeutic doses of drugs, including hydrochlorothiazides and some cytotoxic agents.

### Rare interstitial lung diseases

#### See Box 17.78.

#### Occupational and environmental lung disease

The role of occupation and environmental exposure in lung disease is a particularly important area of respiratory medicine. Occupational lung disease is common and, in addition to the challenges of its diagnosis and management, often involves discussions about the workplace and, in some circumstances, litigation. Many countries encourage the registration of cases of occupational lung disease.

#### Occupational airway disease

### Occupational asthma

Occupational asthma should be considered in any individual of working age who develops new-onset asthma, particularly if the individual reports improvement in asthma symptoms during periods away from work, e.g. at weekends and on holidays. Workers in certain occupations appear to be at particularly high risk (Box 17.79) and the condition is more common in smokers and atopic individuals. Depending on the intensity of exposure, asthmatic symptoms usually develop within the first few years of employment but are classically preceded by a latent period. Symptoms of rhinoconjunctivitis often precede

very high concentrations. Pulmonary function tests show airflow obstruction and airway hyper-reactivity, and the management is similar to that of asthma. Once developed, the condition often persists but it is common for symptoms to improve over years.

Chronic obstructive pulmonary disease

While tobacco smoking remains the most important preventable cause of COPD, there is increasing recognition that other noxious particles and gases can cause, or aggravate, the condition. Occupational COPD is recognised in workers exposed to coal dust, crystalline silica and cadmium. In many parts of the developing world, indoor air pollution from the burning of biomass fuels in confined spaces used for cooking contributes to the development of COPD.

Byssinosis

Byssinosis occurs in workers of cotton and flax mills exposed to cotton brack (dried leaf and plant debris). An acute form of the disease may occur, but more typically, byssinosis develops after 20–30 years’ exposure. Typical symptoms include chest tightness or breathlessness accompanied by a drop in lung function; classically, these are most severe on the first day of the working week (‘Monday fever’) or on return to work following a period away. As the week progresses, symptoms improve and the fall in lung function becomes less dramatic. Continued exposure leads to the development of persistent symptoms and a progressive decline in FEV₁, similar to that observed in COPD.

Pneumoconiosis

Pneumoconiosis may be defined as a permanent alteration of lung structure due to the inhalation of mineral dust and the tissue reactions of the lung to its presence, excluding bronchitis and emphysema. Not all dusts are pathogenic. For example, silica is highly fibrogenic, whereas iron (siderosis), tin (stannosis) and barium (baritosis) are almost inert. Beryllium causes an interstitial granulomatous disease similar to sarcoidosis. In

Fig. 17.61 Peak flow readings in occupational asthma. In this example, an individual with suspected occupational asthma has performed serial peak flow recording both at and away from work. The maximum, mean and minimum values are plotted daily. Days at work are indicated by the shaded areas. The diurnal variation is displayed at the top. Here, a period away from work is followed by a marked improvement in peak flow readings and a reduction in diurnal variation. (PEF = peak expiratory flow)

Lung diseases caused by exposure to inorganic dusts may develop (Fig. 17.62). Enlargement of the hilar glands with an ‘egg-shell’ pattern of calcification is said to be characteristic but is non-specific. Silica is highly fibrogenic and the disease is usually progressive, even when exposure ceases; hence the affected worker should invariably be removed from further exposure. Individuals with silicosis are at increased risk of TB.

### Coal worker’s pneumoconiosis

Coal worker’s pneumoconiosis (CWP) follows prolonged inhalation of coal dust. Dust-laden alveolar macrophages aggregate to form macules in or near the centre of the secondary pulmonary lobule and a fibrotic reaction ensues, resulting in the appearance of scattered discrete fibrotic lesions. Classification is based on the size and extent of radiographic nodularity. Simple coal worker’s pneumoconiosis (SCWP) refers to the appearance of small radiographic nodules in an otherwise asymptomatic individual. SCWP does not impair lung function and, once exposure ceases, will seldom progress. Progressive massive fibrosis (PMF) refers to the formation of conglomerate masses (mainly in the upper lobes), which may cavitate. The development of PMF is usually associated with cough, sputum that may be black (melanoptysis) and breathlessness. The chest X-ray appearances may be confused with lung cancer, TB and granulomatosis with polyangiitis. PMF may progress, even after coal dust exposure ceases, and in extreme cases leads to respiratory failure and right ventricular failure.

Caplan’s syndrome describes the coexistence of rheumatoid arthritis and rounded fibrotic nodules 0.5–5 cm in diameter. They show pathological features similar to a rheumatoid nodule, including central necrosis, palisading histiocytes, and a peripheral rim of lymphocytes and plasma cells. This syndrome may also occur in other types of pneumoconiosis.

### Silicosis

Silicosis results from the inhalation of crystalline silica, usually in the form of quartz, by workers cutting, grinding and polishing stone. Classic silicosis is most common and usually manifests after 10–20 years of continuous silica exposure, during which time the patient remains asymptomatic. Accelerated silicosis is associated with a much shorter duration of dust exposure (typically 5–10 years), may present as early as after 1 year of exposure and, as the name suggests, follows a more aggressive course. Intense exposure to very fine crystalline silica dust can cause a more acute disease: silicoproteinosis, similar to alveolar proteinosis (see Box 17.78).

Radiological features are similar to those of CWP, with multiple well-circumscribed 3–5 mm nodular opacities predominantly in the mid- and upper zones. As the disease progresses, PMF
Berylliosis

Exposure to beryllium is encountered in the aerospace, engineering, telecommunications and biomedical industries. The presence of cough, progressive breathlessness, night sweats and arthralgia in a worker exposed to dusts, fumes or vapours containing beryllium should raise suspicion of berylliosis. The radiographic appearances are similar in type and distribution to those of sarcoid and biopsy shows sarcoid-like granulomas. The diagnosis may be confirmed by specialised tests of lymphocyte function.

Less common pneumoconioses

Siderosis refers to the development of a benign iron oxide pneumoconiosis in welders and other iron foundry workers. Baritosis may be seen in barium process workers and stannosis resembles silicosis but stains the lung red. Diamond polishers in tin refining. Haematite lung occurs in iron ore miners and workers exposed to aluminium oxide develop bauxite pneumoconiosis, sometimes referred to as shaver’s disease. Popcorn worker’s lung is a form of obliterative bronchiolitis following ingestion of diacetyl used in butter flavouring.

Lung diseases due to organic dusts

A wide range of organic agents may cause respiratory disorders (Box 17.81). Disease results from a local immune response to animal proteins or fungal antigens in mouldy vegetable matter. Hypersensitivity pneumonitis is the most common of these conditions.

*Presents as hypersensitivity pneumonitis.

Hypersensitivity pneumonitis

Hypersensitivity pneumonitis (HP; also called extrinsic allergic alveolitis) results from the inhalation of a wide variety of organic antigens that give rise to a diffuse immune complex reaction in the walls of alveoli and bronchioles. Common causes include farmer’s lung and bird fancier’s lung. Other examples are shown in Box 17.81. HP is not exclusively occupational or environmental and other important causes include medications (see Box 17.76).

The pathology of HP is consistent with both type III and type IV immunological mechanisms (p. 83). Precipitating IgG antibodies may be detected in the serum and a type III Arthus reaction is believed to occur in the lung, where the precipitation of immune complexes results in activation of complement and an inflammatory response in the alveolar walls, characterised by the influx of mononuclear cells and foamy histiocytes. The presence of poorly formed non-caseating granulomas in the alveolar walls suggests that type IV responses are also important. The distribution of the inflammatory infiltrate is predominantly peribronchiolar. Chronic forms of the disease may be accompanied by fibrosis. For reasons that remain uncertain, there is a lower incidence of HP in smokers compared to non-smokers.

Clinical features

The presentation of HP varies from an acute form to a more indolent pattern in accordance with the antigen load. For example, the farmer exposed to mouldy hay, as occurs when the hay is gathered and stored damp during a wet summer, or the pigeon fancier cleaning a large pigeon loft will, within a few hours, report influenza-like symptoms accompanied by cough, breathlessness and wheeze. The individual with low-level antigen exposure, however, such as the owner of an indoor pet bird, will typically present in a more indolent fashion with slowly progressive breathlessness; in some cases, established fibrosis may be present by the time the disease is recognised. Chest auscultation typically reveals widespread end-inspiratory crackles and squeaks.

Investigations

In cases of acute HP, the chest X-ray typically shows ill-defined patchy airspace shadowing, which, given the systemic features, may be confused with pneumonia. HRCT is more likely to show bilateral ground-glass shadowing and areas of consolidation superimposed on small centrilobular nodular opacities with an upper and middle lobe predominance (Fig. 17.63). In more chronic disease, features of fibrosis, such as volume loss, linear opacities and architectural distortion, appear. In common with other fibrotic diseases, pulmonary function tests show a restrictive ventilatory defect with reduced lung volumes and impaired gas transfer, dynamic tests may detect oxygen desaturation and, in more advanced disease, type I respiratory failure is present at rest.

Diagnosis

The diagnosis of HP is usually based on the characteristic clinical and radiological features, together with the identification of a potential source of antigen at the patient’s home or place of work (Box 17.82). It may be supported by a positive serum precipitin test or by more sensitive serological investigations. It is important, however, to be aware that the presence of precipitins in the absence of other features does not make the diagnosis; the great majority of farmers with positive precipitins do not have farmer’s lung, and up to 15% of pigeon breeders may have positive serum precipitins yet remain healthy.
Occupational and environmental lung disease

• Hobbies (e.g. pigeon breeders). Dust masks with appropriate filters may minimise exposure and may be combined with methods of reducing levels of antigen (e.g. drying hay before storage). In acute cases, prednisolone should be given for 3–4 weeks, starting with an oral dose of 40 mg per day. Severely hypoxaemic patients may require high-concentration oxygen therapy initially. Most patients recover completely, but if unchecked, fibrosis may progress to cause severe respiratory disability, hypoxaemia, pulmonary hypertension, cor pulmonale and eventually death.

Inhalation (‘humidifier’) fever

Inhalation fever shares similarities with HP. It occurs as a result of contaminated humidifiers or air-conditioning units that release a fine spray of microorganisms into the atmosphere. The illness is characterised by self-limiting fever and breathlessness; permanent sequelae are unusual. An identical syndrome can also develop after disturbing an accumulation of mouldy hay, compost or mulch. So-called ‘hot tub lung’ appears to be attributable to *Mycobacterium avium*. Outbreaks of HP in workers using metalworking fluids appear to be linked to *Acinetobacter* or *Ochrobactrum*.

Asbestos-related lung and pleural diseases

Asbestos is a naturally occurring silicate. Asbestos fibres may be classified as either chrysotile (white asbestos), which accounts for 90% of the world’s production, or serpentine (crocidolite or blue asbestos, and amosite or brown asbestos). The favourable thermal and chemical insulation properties led to its extensive use by the shipbuilding and construction industries throughout the latter part of the 20th century. Exposure to asbestos may be followed, after a lengthy latent period, by the development of both pleural and pulmonary disease.

Pleural plaques

Pleural plaques are the most common manifestation of past asbestos exposure, being discrete circumscribed areas of hyaline fibrosis situated on the parietal pleura of the chest wall.
diaphragm, pericardium or mediastinum. They are virtually always asymptomatic, usually being identified as an incidental finding on a chest X-ray (Fig. 17.64) or thoracic CT scan, particularly when partially calcified. They do not cause impairment of lung function and are benign.

**Acute benign asbestos pleurisy**

Benign asbestos pleurisy is estimated to occur in around 20% of asbestos workers but many episodes are subclinical and pass unreported. When symptomatic, patients present with features of pleurisy, including mild fever and systemic disturbance. The diagnosis therefore necessitates the exclusion of other known causes of pleurisy and pleural effusion. Repeated episodes may be followed by the development of diffuse (visceral) pleural thickening.

**Diffuse pleural thickening**

Diffuse pleural thickening (DPT) refers to thickening of the visceral pleura. In contrast to pleural plaques, if this is sufficiently extensive, it may cause restrictive lung function impairment, exertional breathlessness and, occasionally, persistent chest pain. The typical appearances of DPT on chest X-ray include thickening of the pleura along the chest wall and obliteration of the costophrenic angles. Earlier manifestations detected by CT scanning include parenchymal bands (Fig. 17.65) and ‘round atelectasis’. There is no treatment and the condition may be progressive in around one-third of individuals. In exceptionally severe cases, surgical decortication may be considered. A pleural biopsy may be required to exclude mesothelioma.

**Asbestosis**

Fibrosis of the lung following asbestos exposure generally requires substantial exposure over several years and is rarely associated with low-level or bystander exposure. In common with other fibrosing lung diseases, asbestosis usually presents with exertional breathlessness and fine, late inspiratory crackles over the lower zones. Finger clubbing may be present. Pulmonary function tests and HRCT appearances are similar to those of UIP. These features, accompanied by a history of substantial asbestos exposure, are generally sufficient to establish the diagnosis and lung biopsy is rarely necessary. When biopsy is performed, asbestos may be diagnosed when alveolar septal fibrosis is accompanied by an average of at least two asbestos bodies per square centimetre of lung tissue. In some cases, asbestos fibre counts may be performed on lung biopsy material to establish the diagnosis.

Asbestosis is usually slowly progressive and has a better prognosis than IPF, but in advanced cases respiratory failure, pulmonary hypertension and cor pulmonale may still develop. About 40% of patients (who usually smoke) develop lung cancer and 10% may develop mesothelioma.

**Mesothelioma**

Mesothelioma is a malignant tumour affecting the pleura or, less commonly, the peritoneum. Its occurrence almost invariably suggests past asbestos exposure, which may be low-level. There is typically a long latent interval between first exposure and the onset of clinical manifestations, and this accounts for the continued increasing incidence many years after control measures have been implemented. Around 1 in 170 of all British men born in the 1940s will die of mesothelioma.

Pleural mesothelioma typically presents with increasing breathlessness resulting from pleural effusion or unremitting chest pain, reflecting involvement of the chest wall. As the tumour progresses, it encases the underlying lung and may invade the parenchyma, the mediastinum and the pericardium. Metastatic disease, although not often clinically detectable in life, is a common finding on postmortem.

Mesothelioma is almost invariably fatal. Highly selected patients may be considered for radical surgery but, in the majority of patients, therapy is invariably directed towards palliation of symptoms. The use of chemotherapy may improve quality of life and is accompanied by a small survival benefit, typically regarded as being around 3 months. Radiotherapy can be used to control pain and limit the risk of tumour seeding at biopsy sites. Pleural effusions are managed with drainage and pleurodesis. Typical figures for survival from onset of symptoms are around 16 months for epithelioid tumours, 10 months for sarcomatoid tumours and 15 months for biphasic tumours, with only a minority of patients surviving for longer periods.

**Occupational lung cancer**

Individuals exposed to substantial quantities of asbestos are at increased risk of lung cancer, particularly if they smoke tobacco. Increased risks of lung cancer have also been reported in workers who develop silicosis and those exposed to radon gas, beryllium, diesel exhaust fumes, cadmium, chromium, and dust and fumes from coke plants.

**Occupational pneumonia**

Occupational and environmental exposures may be linked to the development of pneumonia. Pneumococcal vaccine is recommended for welders. Farm workers, abattoir workers and hide factory workers may be exposed to *Coxiella burnetii*, the causative agent of Q fever. The organisms are excreted from milk, urine, faeces and amniotic fluid; they may be transmitted by cattle ticks or contaminated dust from the milking floor, or by drinking milk that is inadequately pasteurised. Birds (often parrots) or budgerigars infected with *Chlamydia psittaci* can cause psittacosis. Sewage workers, farmers, animal handlers and vets run an increased risk of leptospiral pneumonia, and contact...
Pulmonary vascular disease

Pulmonary embolism

The majority of pulmonary emboli arise from the propagation of lower limb deep vein thrombosis (p. 186). Rare causes include septic emboli (from endocarditis affecting the tricuspid or pulmonary valves), tumour (especially choriocarcinoma), fat following fracture of long bones such as the femur, air, and amniotic fluid, which may enter the mother's circulation following delivery.

Clinical presentation varies, depending on number, size and distribution of emboli and on underlying cardiorespiratory reserve (Box 17.83). A recognised risk factor is present in 80–90% (see Box 23.65, p. 975). The presence of one or more risk factors increases the risk further still.

Investigations

A variety of non-specific radiographic appearances have been described (Fig. 17.66) but the chest X-ray is most useful in

![Fig. 17.66 Features of pulmonary thromboembolism/infarction on chest X-ray.](image)
excluding key differential diagnoses, e.g. pneumonia or pneumothorax. Normal appearances in an acutely breathless and hypoxaemic patient should raise the suspicion of PE, as should bilateral changes in anyone presenting with unilateral pleuritic chest pain.

The ECG is often normal but is useful in excluding other important differential diagnoses, such as acute myocardial infarction and pericarditis. The most common findings in PE include sinus tachycardia and anterior T-wave inversion but these are non-specific; larger emboli may cause right heart strain revealed by an S1Q3T3 pattern, ST-segment and T-wave changes, or the appearance of right bundle branch block.

Arterial blood gases typically show a reduced PaO₂ and a normal or low PaCO₂, and an increased alveolar–arterial oxygen gradient, but may be normal in a significant minority. A metabolic acidosis may be seen in acute massive PE with cardiovascular collapse.

An elevated D-dimer (see Fig. 10.6, p. 187) is of limited value, as it may be raised in a variety of other conditions, including myocardial infarction, pneumonia and sepsis. However, low levels, particularly in the context of a low clinical risk, have a high negative predictive value and further investigation is usually unnecessary (Fig. 17.67). The result of the D-dimer assay should be disregarded in high-risk patients, as further investigation is mandatory even when normal. The serum troponin I (see Box 10.3, p. 179) may be elevated, reflecting right heart strain.

CTPA is the first-line diagnostic test (Fig. 17.68). It has the advantage of visualising the distribution and extent of the emboli or highlighting an alternative diagnosis, such as consolidation, pneumothorax or aortic dissection. The sensitivity of CT scanning may be increased by simultaneous visualisation of the femoral and popliteal veins, although this is not widely practised. As the contrast media may be nephrotoxic, care should be taken in patients with renal impairment, and CTPA avoided in those with a history of allergy to iodinated contrast media. In these cases, either V/Q scanning or ventilation/perfusion single photon emission computed tomography (V/Q SPECT) may be considered.

Fig. 17.67 Algorithm for the investigation of patients with suspected pulmonary thromboembolism. Clinical risk is based on the presence of risk factors for venous thromboembolism and the probability of another diagnosis. (DVT = deep vein thrombosis; PE = pulmonary embolism)

Colour Doppler ultrasound of the leg veins may be used in patients with suspected PE, particularly if there are clinical signs in a limb, as many will have identifiable proximal thrombus in the leg veins.

Bedside echocardiography is extremely helpful in the differential diagnosis and assessment of acute circulatory collapse (p. 199). Acute dilatation of the right heart is usually present in massive PE, and thrombus (embolism in transit) may be visible. Important differential diagnoses, including left ventricular failure, aortic dissection and pericardial tamponade, can also be identified.

Conventional pulmonary angiography is still useful in selected settings or for the delivery of catheter-based therapies.

Management

General measures

Prompt recognition and treatment are potentially life-saving. Sufficient oxygen should be given to hypoxaemic patients to maintain arterial oxygen saturation above 90%. Circulatory shock should be treated with intravenous fluids or plasma expander, but inotropic agents are of limited value as the hypoxic dilated right ventricle is already close to maximally stimulated by endogenous catecholamines. Diuretics and vasodilators should also be avoided, as they will reduce cardiac output. Opiates may be necessary to relieve pain and distress but should be used with caution.

Fig. 17.68 CT pulmonary angiogram. The arrow points to a saddle embolism in the bifurcation of the pulmonary artery.

17.84 Pulmonary embolism in pregnancy

- Maternal mortality: venous thromboembolism is the leading direct cause in the UK.
- CT pulmonary angiography: may be performed safely (0.01–0.06 mGy). It is important to consider the risk of radiation to breast tissue (particularly if there is a family history of breast carcinoma).
- V/Q scanning: greater radiation dose to fetus (0.11–0.22 mGy) but significantly less to maternal breast tissue.
- In utero radiation exposure: estimated incidence of childhood malignancy is about 1 in 16 000 per mGy.
- Warfarin: teratogenic, so pulmonary embolism should be treated with low-molecular-weight heparin during pregnancy.
in the hypotensive patient. External cardiac massage may be successful in the moribund patient by dislodging and breaking up a large central embolus.

Anticoagulation
The main principle of treatment for PE is anticoagulation, which is discussed for PE and other forms of VTE on page 975.

Thrombolytic and surgical therapy
Thrombolysis is indicated in any patient presenting with acute massive PE accompanied by cardiogenic shock. In the absence of shock, the benefits are less clear but thrombolysis may be considered in those presenting with right ventricular dilatation and hypokinesis or severe hypoxaemia. Patients must be screened carefully for haemorrhagic risk, as there is a high risk of intracranial haemorrhage. Surgical pulmonary embolectomy may be considered in selected patients but carries a high mortality.

Caval filters
A patient in whom anticoagulation is contraindicated, who has suffered massive haemorrhage on anticoagulation, or recurrent VTE despite anticoagulation, should be considered for an inferior vena caval filter. Retrievable caval filters are particularly useful in individuals with temporary risk factors. The caval filter should be used only until anticoagulation can be safely initiated, at which time the filter should be removed if possible.

Prognosis
Immediate mortality is greatest in those with echocardiographic evidence of right ventricular dysfunction or cardiogenic shock. Once anticoagulation is commenced, however, the risk of mortality rapidly falls. The risk of recurrence is highest in the first 6–12 months after the initial event, and at 10 years around one-third of individuals will have suffered a further event.

Pulmonary hypertension
Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure (PAP) of at least 25 mmHg at rest, as measured by right heart catheterisation. The definition may be further refined by consideration of the pulmonary wedge pressure (PWP), the cardiac output and the transpulmonary pressure gradient (mean PAP – mean PWP). The clinical classification of PH is shown in Box 17.85. Further classification is based on the degree of functional disturbance, assessed using the New York Heart Association (NYHA) grades I–IV. Although respiratory failure due to intrinsic pulmonary disease is the most common cause of PH, severe PH may occur as a primary disorder, as a complication of connective tissue disease (e.g. systemic sclerosis), or as a result of chronic thromboembolic events.

Primary pulmonary hypertension (PPH) is a rare but important disease that predominantly affects women aged between 20 and 30 years. Familial disease is rarer still but is known to be associated with mutations in the gene encoding type II bone morphogenetic protein receptor (BMPR2), a member of the transforming growth factor beta (TGF-β) superfamily. Mutations in this gene have been identified in some patients with sporadic PH. Pathological features include hypertrophy of both the media and the intima of the vessel wall and a clonal expansion of endothelial cells, which take on the appearance of pleiform lesions. There is marked narrowing of the vessel lumen and this, together with the frequently observed in situ thrombosis, leads to an increase in pulmonary vascular resistance and PH.

Clinical features
PH presents insidiously and is often diagnosed late. Typical symptoms include breathlessness, chest pain, fatigue, palpitation and syncope. Important signs include elevation of the JVP (with a prominent ‘a’ wave if in sinus rhythm), a parasternal heave (right ventricular hypertrophy), accentuation of the pulmonary component of the second heart sound and a right ventricular third heart sound. Signs of interstitial lung disease or cardiac, liver or connective tissue disease may suggest the underlying cause.

Investigations
PH is suspected if an ECG shows a right ventricular ‘strain’ pattern or a chest X-ray shows enlarged pulmonary arteries, peripheral pruning and right ventricle enlargement (Fig. 17.69). Doppler assessment of the tricuspid regurgitant jet by transthoracic echocardiography provides a non-invasive estimate of the PAP, which is equal to $4 \times$ (tricuspid regurgitation velocity)$^2$. Further assessment should be by right heart catheterisation to assess pulmonary haemodynamics, measure vasodilator responsiveness and thus guide further therapy.

Management
Specialist centres should direct the management of PH. Diuretic therapy should be prescribed for patients with right heart failure. Supplemental oxygen should be given to maintain resting $\text{PaO}_2$. 

### Classification of pulmonary hypertension

**Pulmonary arterial hypertension**
- Primary pulmonary hypertension: sporadic and familial
- Secondary to: connective tissue disease (limited cutaneous systemic sclerosis), congenital systemic to pulmonary shunts, portal hypertension, HIV infection, exposure to various drugs or toxins, and persistent pulmonary hypertension of the newborn

**Pulmonary venous hypertension**
- Left-sided atrial or ventricular heart disease
- Left-sided valvular heart disease
- Pulmonary veno-occlusive disease
- Pulmonary capillary haemangiomatosis

**Pulmonary hypertension associated with disorders of the respiratory system and/or hypoxaemia**
- Chronic obstructive pulmonary disease
- Diffuse parenchymal lung disease
- Sleep-disordered breathing
- Alveolar hypoventilation disorders
- Chronic exposure to high altitude
- Neonatal lung disease
- Alveolar capillary dysplasia
- Severe kyphoscoliosis

**Pulmonary hypertension caused by chronic thromboembolic disease**
- Thromboembolic obstruction of the proximal pulmonary arteries
- In situ thrombosis
- Sickle-cell disease

**Miscellaneous**
- Inflammatory conditions
- Extrinsic compression of central pulmonary veins

Diseases of the upper airway

Diseases of the nasopharynx

Allergic rhinitis

This is a disorder in which there are episodes of nasal congestion, watery nasal discharge and sneezing. It may be seasonal or perennial, and is due to an immediate hypersensitivity reaction in the nasal mucosa. Seasonal antigens include pollens from grasses, flowers, weeds or trees. Grass pollen is responsible for hay fever, the most common type of seasonal allergic rhinitis in northern Europe, which is at its peak between May and July.

High-dose calcium channel blockers may be appropriate in those with chronic proximal pulmonary thromboembolic disease. Atrial septostomy (the creation of a right-to-left shunt) may be contemplated with an acute vasodilator response.

Sildenafil or tadalafil, or the guanylate cyclase stimulator riociguat. Vasodilatation with phosphodiesterase V inhibitors, such as tadalafil, or macitentan; or enhancing endogenous nitric oxide-mediated vasoconstriction with agents such as bosentan, ambrisentan, treprostinil or nebulised iloprost; blocking endothelin-mediated endogenous prostacyclins with infusions of epoprostenol or iloprost; or enhancing endogenous nitric oxide-mediated vasoconstriction with agents such as riociguat

Cyclizine can aggravate PH and should be avoided. Dihydropyridine calcium channel blockers are poorly tolerated. Cyclizine can aggravate PH and should also be avoided.

Disease-targeted strategies have focused on replacing endogenous prostacyclins with infusions of epoprostenol or treprostinil or nebulised iloprost; blocking endothelin-mediated vasoconstriction with agents such as bosentan, ambrisentan or macitentan; or enhancing endogenous nitric oxide-mediated vasodilatation with phosphodiesterase V inhibitors, such as sildenafil or tadalafil, or the guanylate cyclase stimulator riociguat. High-dose calcium channel blockers may be appropriate in those with an acute vasodilator response.

Selected patients are referred for double-lung transplantation, and pulmonary thromboendarterectomy may be contemplated in those with chronic proximal pulmonary thromboembolic disease. Atrial septostomy (the creation of a right-to-left shunt) decompresses the right ventricle and improves haemodynamic performance; it may be used as a bridge to transplantation or as a palliative measure.

This is a worldwide problem, however, which may be aggravated during harvest seasons.

Perennial allergic rhinitis may be a specific reaction to antigens derived from house dust, fungal spores or animal dander, but similar symptoms can be caused by physical or chemical irritants, e.g. pungent odours or fumes, including strong perfumes, cold air and dry atmospheres. The phrase ‘vasomotor rhinitis’ is often used in this context, as the term ‘allergic’ is a misnomer.

Clinical features

In the seasonal type, there are frequent sudden attacks of sneezing, with profuse watery nasal discharge and nasal obstruction. These attacks last for a few hours and are often accompanied by smarting and watering of the eyes and conjunctival irritation. In perennial rhinitis, the symptoms are similar but more continuous and usually less severe. Skin hypersensitivity tests with the relevant antigen are usually positive in seasonal allergic rhinitis but are less useful in perennial rhinitis.

Management

In those sensitised to house dust, simple measures, such as thorough dust removal from the bed area, leaving a window open and renewing old pillows, are often helpful. Avoidance of pollen and antigens from domestic pets, however desirable and beneficial, is usually impractical.

The following medications, singly or in combination, are usually effective in both seasonal and perennial allergic rhinitis:

- an antihistamine such as loratadine
- sodium cromoglicate nasal spray
- glucocorticoid nasal spray, e.g. beclometasone dipropionate, fluticasone, mometasone or budesonide.

When symptoms are very severe, resistant to usual treatments and seriously interfering with school, business or social activities, immunotherapy (desensitisation) is also used but carries the risk of serious reactions and must be managed in specialist centres. Vasomotor rhinitis is often difficult to treat but may respond to ipratropium bromide, administered into each nostril 3 times daily.

Sleep-disordered breathing

A variety of respiratory disorders affect sleep or are affected by sleep. Cough and wheeze disturbing sleep are characteristic of asthma, while the hypoventilation that accompanies normal sleep can precipitate respiratory failure in patients with disordered ventilation due to kyphoscoliosis, diaphragmatic paralysis or muscle disease (e.g. muscular dystrophy).

In contrast, a small but important group of disorders cause problems only during sleep. Patients may have normal lungs and daytime respiratory function, but during sleep have either abnormalities of ventilatory drive (central sleep apnoea/hypopnoea syndrome) or upper airway obstruction (obstructive sleep apnoea). Of these, the obstructive sleep apnoea/hypopnoea syndrome is by far the most common and important. When this coexists with COPD, severe respiratory failure can result, even if the COPD is mild.

The sleep apnoea/hypopnoea syndrome

Recurrent upper airway obstruction during sleep, sufficient to cause sleep fragmentation and daytime sleepiness, is thought to affect 2% of women and 4% of men aged 30–60 in Caucasian populations. Daytime sleepiness, especially in monotonous situations, results in a threefold increased risk of road traffic accidents and a ninefold increased risk of single-vehicle accidents.
**Aetiology**

Sleep apnoea results from recurrent occlusion of the pharynx during sleep, usually at the level of the soft palate. Inspiration results in negative pressure within the pharynx. During wakefulness, upper airway dilating muscles, including palatoglossus and genioglossus, contract actively during inspiration to preserve airway patency. During sleep, muscle tone declines, impairing the ability of these muscles to maintain pharyngeal patency. In a minority of people, a combination of an anatomically narrow palatopharynx and under-activity of the dilating muscles during sleep results in inspiratory airway obstruction. Incomplete obstruction causes turbulent flow, resulting in snoring (44% of men and 28% of women aged 30–60 snore). More severe obstruction triggers increased inspiratory effort and transiently wakes the patient, allowing the dilating muscles to re-open the airway. These awakenings are so brief that patients have no recollection of them. After a series of loud deep breaths that may wake their bed partner, the patient rapidly returns to sleep, snores and becomes apnoeic once more. This cycle of apnoea and awakening may repeat itself many hundreds of times per night and results in severe sleep fragmentation and secondary variations in blood pressure, which may predispose over time to cardiovascular disease.

Predisposing factors to the sleep apnoea/hypopnoea syndrome include male gender, which doubles the risk, and obesity, which is found in about 50% because parapharyngeal fat deposits tend to narrow the pharynx. Nasal obstruction or a recessed mandible can further exacerbate the problem. Acromegaly and hypothyroidism also predispose by causing submucosal infiltration and narrowing of the upper airway. Sleep apnoea is often familial, where the maxilla and mandible are back-set, narrowing the upper airway. Alcohol and sedatives predispose to snoring and apnoea by relaxing the upper airway dilating muscles. As a result of marked sympathetic activation during apnoea, sleep-disordered breathing is associated over time with sustained hypertension and an increased risk of corona events and stroke. Associations have also been described with insulin resistance, the metabolic syndrome and type 2 diabetes. Treatment of sleep apnoea reduces sympathetic drive and blood pressure, and may also improve these associated metabolic disorders.

**Clinical features**

Excessive daytime sleepiness is the principal symptom and snoring is virtually universal. The patient usually feels that he or she has been asleep all night but wakes unrefreshed. Bed partners report loud snoring in all body positions and often have noticed multiple breathing pauses (apnoeas). Difficulty with concentration, impaired cognitive function and work performance, depression, irritability and nocturia are other features.

**Investigations**

Provided that the sleepiness does not result from inadequate time in bed or from shift work, anyone who repeatedly falls asleep during the day when not in bed, who complains that his or her work is impaired by sleepiness, or who is a habitual snorer with multiple witnessed apnoeas should be referred for a sleep assessment. A more quantitative assessment of daytime sleepiness can be obtained by questionnaire (Box 17.86).

Overnight studies of breathing, oxygenation and sleep quality are diagnostic (Fig. 17.70) but the level of investigation depends on local resources and the probability of the diagnosis. The current threshold for diagnosing moderate sleep apnoea/hypopnoea syndrome is 15 or more apnoeas/hypopnoeas per hour of sleep, where an apnoea is defined as a 10-second or longer breathing pause and a hypopnoea a 10-second or longer 50% reduction in breathing.

Several other conditions can cause daytime sleepiness but can usually be excluded by a careful history (Box 17.87). Narcolepsy is a rare cause of sudden-onset sleepiness, occurring in 0.05% of the population (p. 1105). Idiopathic hypersomnolence occurs in younger individuals and is characterised by long nocturnal sleeps.

**Management**

The major hazard to patients and those around them is traffic accidents, so drivers must be strongly advised not to drive until treatment has relieved their sleepiness. In a minority, relief of nasal obstruction or the avoidance of alcohol may prevent obstruction. Advice to obese patients to lose weight is often unheeded and the majority of patients need to use continuous positive air pressure (CPAP) to relieve their apnoea/hypopnoea.
positive airway pressure (CPAP) delivered by a nasal mask every night to splint the upper airway open. When CPAP is tolerated, the effect is often dramatic (Fig. 17.70), with relief of somnolence and improved daytime performance, quality of life and survival. Unfortunately, 30–50% of patients do not tolerate CPAP. Mandibular advancement devices that fit over the teeth and hold the mandible forward, thus opening the pharynx, are an alternative that is effective in some patients. There is no evidence that palatal surgery is of benefit.

Laryngeal disorders

The larynx is commonly affected by acute self-limiting infections (p. 581). Other disorders include chronic laryngitis, laryngeal tuberculosis, laryngeal paralysis and laryngeal obstruction. Tumours of the larynx are relatively common, particularly in smokers. For further details, the reader should refer to an otolaryngology text.

Chronic laryngitis

The common causes are listed in Box 17.88. The chief symptoms are hoarseness or loss of voice (aphonia). There is irritation of the throat and a spasmodic cough. The disease pursues a chronic course, frequently uninfluenced by treatment, and the voice may become permanently impaired. Other causes of chronic hoarseness include use of inhaled glucocorticoid treatment, tuberculosis, laryngeal paralysis or tumour.

In some patients, a chest X-ray may reveal an unsuspected lung cancer or pulmonary tuberculosis. If these are not found, laryngoscopy should be performed to exclude a local structural cause.

When no specific treatable cause is found, the voice must be rested completely. This is particularly important in public speakers and singers. Smoking should be avoided. Some benefit may be obtained from frequent inhalations of medicated steam.

Laryngeal paralysis

 Interruption of the motor nerve supply of the larynx is nearly always unilateral and, because of the intrathoracic course of the left recurrent laryngeal nerve, usually left-sided. One or both recurrent laryngeal nerves may be damaged by thyroidectomy, carcinoma of the thyroid or anterior neck injury. Rarely, the vagal trunk itself is involved by tumour, aneurysm or trauma.

Clinical features and management

Hoarseness always accompanies laryngeal paralysis, whatever its cause. Paralysis of organic origin is seldom reversible, but when only one vocal cord is affected, hoarseness may improve or even disappear after a few weeks, as the normal cord compensates for the paralyzed cord on phonation.

‘Bovine cough’ is a characteristic feature of organic laryngeal paralysis, and lacks the explosive quality of normal coughing because the cords fail to close the glottis. Sputum clearance may also be impaired. A normal cough in patients with partial loss of voice or aphonia virtually excludes laryngeal paralysis. Stridor is occasionally present but seldom severe, except when laryngeal paralysis is bilateral.

Laryngoscopy is required to establish the diagnosis of laryngeal paralysis. The paralysed cord lies in the so-called ‘cadaveric’ position, midway between abduction and adduction.

The cause should be treated, if possible. In unilateral paralysis, persistent dysphonia may be improved by the injection of Teflon into the affected vocal cord. In bilateral organic paralysis, tracheal intubation, tracheostomy or plastic surgery on the larynx may be necessary.

Psychogenic hoarseness and aphonia

Psychogenic causes of hoarseness or aphonia may be suggested by associated symptoms in the history (p. 1187). Laryngoscopy may be necessary, however, to exclude a physical cause. In psychogenic aphonia, only the voluntary movement of adduction of the vocal cords is seen to be impaired. Speech therapy may be helpful.

Laryngeal obstruction

Laryngeal obstruction is more likely to occur in children than in adults because of the smaller size of the glottis. Important causes are given in Box 17.89. Sudden complete laryngeal obstruction by a foreign body produces the clinical picture of acute asphyxia:
Tracheal disorders

Tracheal obstruction

External compression by lymph nodes containing metastases, usually from a lung cancer, is a more frequent cause of tracheal obstruction than primary benign or malignant tumours. The trachea may also be compressed by a retrosternal goitre (see Fig. 17.71, p. 648). Rare causes include an aneurysm of the aortic arch and (in children) tuberculous mediastinal lymph nodes. Tracheal stenosis is an occasional complication of tracheostomy, prolonged intubation, granulomatosis with polyangitis (Wegener’s granulomatosis; p. 1041) or trauma.

Clinical features and management

Stridor can be detected in every patient with severe tracheal narrowing. Bronchoscopic examination of the trachea should be undertaken without delay to determine the site, degree and nature of the obstruction.

Localised tumours of the trachea can be resected but reconstruction after resection may be technically difficult. Endobronchial laser therapy, bronchoscopically placed tracheal stents, chemotherapy and radiotherapy are alternatives to surgery. The choice of treatment depends on the nature of the tumour and the general health of the patient. Benign tracheal strictures can sometimes be dilated but may require resection.

Tracheo-oesophageal fistula

This may be present in newborn infants as a congenital abnormality. In adults, it is usually due to malignant lesions in the mediastinum, such as carcinoma or lymphoma, eroding both the trachea and oesophagus to produce a communication between them. Swallowed liquids enter the trachea and bronchi through the fistula and provoke coughing.

Surgical closure of a congenital fistula, if undertaken promptly, is usually successful. There is usually no curative treatment for malignant fistulae, and death from overwhelming pulmonary infection rapidly supervenes.

Pleural disease

Pleurisy, pleural effusion, empyema and asbestos-associated pleural disease have been described above.

Pneumothorax

Pneumothorax is the presence of air in the pleural space, which can either occur spontaneously, or result from iatrogenic injury or trauma to the lung or chest wall (Box 17.90). Primary spontaneous pneumothorax occurs in patients with no history of lung disease. Smoking, tall stature and the presence of apical subpleural blebs are risk factors. Secondary pneumothorax affects patients with pre-existing lung disease and is associated with higher mortality rates (Fig. 17.71).

Where the communication between the airway and the pleural space seals off as the lung deflates and does not re-open, the...
pneumothorax is referred to as ‘closed’ (Fig. 17.72A). The mean pleural pressure remains negative, spontaneous reabsorption of air and re-expansion of the lung occur over a few days or weeks, and infection is uncommon. This contrasts with an ‘open’ pneumothorax, where the communication fails to seal and air continues to pass freely between the bronchial tree and pleural space (Fig. 17.72B). An example of the latter is a bronchopleural fistula, which can facilitate the transmission of infection from the airways into the pleural space, leading to empyema. An open pneumothorax is commonly seen following rupture of an emphysematous bulla, tuberculous cavity or lung abscess into the pleural space.

Occasionally, the communication between the airway and the pleural space acts as a one-way valve, allowing air to enter the pleural space during inspiration but not to escape on expiration. This is a tension pneumothorax. Large amounts of trapped air accumulate progressively in the pleural space and the intrapleural pressure rises to well above atmospheric levels. This causes mediastinal displacement towards the opposite side, with compression of the opposite normal lung and impairment of systemic venous return, causing cardiovascular compromise (Fig. 17.72C).

**Clinical features**

The most common symptoms are sudden-onset unilateral pleuritic chest pain or breathlessness. In those individuals with underlying lung disease, breathlessness can be severe and may not resolve spontaneously. In patients with a small pneumothorax, physical examination may be normal. A larger pneumothorax (>15% of the hemithorax) results in decreased or absent breath sounds (p. 547). The combination of absent breath sounds and a resonant percussion note is diagnostic of pneumothorax.

By contrast, in tension pneumothorax there is rapid progressive breathlessness associated with a marked tachycardia, hypotension, cyanosis and tracheal displacement away from the side of the silent hemithorax. Occasionally, tension pneumothorax may occur without mediastinal shift, if malignant disease or scarring has splinted the mediastinum.

**Investigations**

The chest X-ray shows the sharply defined edge of the deflated lung with complete translucency (no lung markings) between this and the chest wall (p. 547). Care must be taken to differentiate between a large pre-existing emphysematous bulla and a pneumothorax. CT is used in difficult cases to avoid misdirected attempts at aspiration. X-rays may also show the extent of any mediastinal displacement and reveal any pleural fluid or underlying pulmonary disease.

**Management**

Primary pneumothorax, in which the lung edge is less than 2 cm from the chest wall and the patient is not breathless, normally resolves without intervention. In young patients presenting with a moderate or large spontaneous primary pneumothorax, percutaneous needle aspiration of air is a simple and well-tolerated alternative to intercostal tube drainage, with a 60–80% chance of avoiding the need for a chest drain (Fig. 17.73). In patients with significant underlying chronic lung disease, however, secondary pneumothorax may cause respiratory distress. In these individuals, the success rate of aspiration is much lower, and intercostal tube drainage and inpatient observation are usually required, particularly in those over 50 years old and those with respiratory compromise. If there is a tension pneumothorax, immediate release of the positive pressure by insertion of a blunt cannula into the pleural space may be beneficial, allowing time to prepare for chest drain insertion.

When needed, intercostal drains are inserted in the fourth, fifth or sixth intercostal space in the mid-axillary line, connected to an underwater seal or one-way Heimlich valve, and secured firmly.
to the chest wall. Clamping of an intercostal drain is potentially dangerous and rarely indicated. The drain should be removed the morning after the lung has fully re-inflated and bubbling has stopped. Continued bubbling after 5–7 days is an indication that the drain should be removed. Continued bubbling after 5–7 days is an indication that the drain should be removed.

Acquired disorders

Elevation of a hemidiaphragm may result from paralysis or other structural causes (Box 17.92). The phrenic nerve may be damaged by lung cancer, disease of cervical vertebrae, tumours of the cervical cord, shingles, trauma (including road traffic and birth injuries), surgery, and stretching of the nerve by mediastinal masses and aortic aneurysms. Idiopathic diaphragmatic paralysis occasionally occurs in otherwise fit patients. Paralysis of one hemidiaphragm results in loss of around 20% of ventilatory capacity but may not be noticed by otherwise healthy individuals. Ultrasound screening can be used to demonstrate paradoxical upward movement of the paralysed hemidiaphragm on sniffing. CT of the chest and neck is the best way to exclude occult disease affecting the phrenic nerve.

Bilateral diaphragmatic weakness occurs in peripheral neuropathies of any type, including Guillain–Barré syndrome (p. 1140); in disorders affecting the anterior horn cells, e.g. poliomyelitis (p. 1123); in muscular dystrophies; and in connective tissue disorders, such as SLE and polymyositis (pp. 1034 and 1039).

Hiatus hernia is common (p. 791). Diaphragmatic rupture is usually caused by a crush injury and may not be detected until years later. Respiratory disorders that cause pulmonary hyperinflation, e.g. emphysema, and those that result in small stiff lungs, e.g. diffuse pulmonary fibrosis, compromise diaphragmatic function and predispose to fatigue.

### Disorders of the diaphragm

#### Congenital disorders

**Diaphragmatic hernias**

Congenital defects of the diaphragm can allow herniation of abdominal viscera. Posteriorly situated hernias through the foramen of Bochdalek are more common than anterior hernias through the foramen of Morgagni.

**Eventration of the diaphragm**

Abnormal elevation or bulging of one hemidiaphragm, more often the left, results from total or partial absence of muscular development of the septum transversum. Most eventrations are asymptomatic and are detected by chance on X-ray in adult life but severe respiratory distress can be caused in infancy if the diaphragmatic muscular defect is extensive.

#### Acquired disorders

Elevation of a hemidiaphragm may result from paralysis or other structural causes (Box 17.92). The phrenic nerve may be damaged by lung cancer, disease of cervical vertebrae, tumours of the cervical cord, shingles, trauma (including road traffic and birth injuries), surgery, and stretching of the nerve by mediastinal masses and aortic aneurysms. Idiopathic diaphragmatic paralysis occasionally occurs in otherwise fit patients. Paralysis of one hemidiaphragm results in loss of around 20% of ventilatory capacity but may not be noticed by otherwise healthy individuals. Ultrasound screening can be used to demonstrate paradoxical upward movement of the paralysed hemidiaphragm on sniffing. CT of the chest and neck is the best way to exclude occult disease affecting the phrenic nerve.

Bilateral diaphragmatic weakness occurs in peripheral neuropathies of any type, including Guillain–Barré syndrome (p. 1140); in disorders affecting the anterior horn cells, e.g. poliomyelitis (p. 1123); in muscular dystrophies; and in connective tissue disorders, such as SLE and polymyositis (pp. 1034 and 1039).

Hiatus hernia is common (p. 791). Diaphragmatic rupture is usually caused by a crush injury and may not be detected until years later. Respiratory disorders that cause pulmonary hyperinflation, e.g. emphysema, and those that result in small stiff lungs, e.g. diffuse pulmonary fibrosis, compromise diaphragmatic function and predispose to fatigue.
Deformities of the chest wall

Thoracic kyphoscoliosis

Abnormalities of alignment of the dorsal spine and their consequent effects on thoracic shape may be caused by:

- congenital abnormality
- vertebral disease, including tuberculosis, osteoporosis and ankylosing spondylitis
- trauma
- neuromuscular disease, such as poliomyelitis.

Simple kyphosis (increased anterior curvature of the thoracic spine) causes less pulmonary embarrassment than kyphoscoliosis (anteroposterior and lateral curvature). Kyphoscoliosis, if severe, restricts and distorts expansion of the chest wall and impairs diaphragmatic function, causing ventilation–perfusion mismatch in the lungs. Patients with severe deformity may develop type II respiratory failure (initially manifest during sleep), pulmonary hypertension and right ventricular failure. They can often be successfully treated with non-invasive ventilatory support (p. 202).

Pectus excavatum

Pectus excavatum (funnel chest) is an idiopathic condition in which the body of the sternum, usually only the lower end, is curved inwards. The heart is displaced to the left and may be compressed between the sternum and the vertebral column but only rarely is there associated disturbance of cardiac function. The deformity may restrict chest expansion and reduce vital capacity. Operative correction is rarely performed, and then only for cosmetic reasons.

Pectus carinatum

Pectus carinatum (pigeon chest) is frequently caused by severe asthma during childhood. Very occasionally, this deformity can be produced by rickets or be idiopathic.

Clinical examination in endocrine disease

Endocrine disease causes clinical syndromes with symptoms and signs involving many organ systems. The emphasis of the clinical examination depends on the gland or hormone that is thought to be abnormal.

Diabetes mellitus (described in detail in Ch. 20) and thyroid disease are the most common endocrine disorders.

5 Blood pressure
- Hypertension in Cushing’s and Conn’s syndromes, pheochromocytoma
- Hypotension in adrenal insufficiency

4 Pulse
- Atrial fibrillation
- Sinus tachycardia
- Bradycardia

3 Skin
- Hair distribution
- Dry/greasy
- Pigmentation/pallor
- Bruising
- Vitiligo
- Striae
- Thickness

2 Hands
- Palmar erythema
- Tremor
- Acromegaly
- Carpal tunnel syndrome

1 Height and weight

6 Head
- Eyes: Graves’ disease (see opposite)
- Diplopia
- Visual field defect (see opposite)
- Hair: Alopecia
- Frontal balding

5 Prognathism in acromegaly

3 Vitiligo in organ-specific autoimmune disease

2 Pigmentation of creases due to high ACTH levels in Addison’s disease

1 Acromegalic hands. Note soft tissue enlargement causing ‘spade-like’ changes

1 Observation
- Most examination in endocrinology is by observation
- Astute observation can often yield ‘spot’ diagnosis of endocrine disorders
- The emphasis of examination varies depending on which gland or hormone is thought to be involved

7 Neck
- Voice: Hoarse, e.g. hypothyroid
- Viritised
- Thyroid gland (see opposite)
- Goitre
- Nodules

8 Breasts
- Galactorrhea
- Gynaecomastia

9 Body fat
- Central obesity in Cushing’s syndrome and growth hormone deficiency

10 Bones
- Fragility fractures (e.g. of vertebrae, neck of femur or distal radius)

11 Genitalia
- Viritisation
- Pubertal development
- Testicular volume

12 Legs
- Proximal myopathy
- Myxoedema

1 Pretibial myxoedema in Graves’ disease
6 Examination of the visual fields by confrontation

- Sit opposite patient
- You and patient cover opposite eyes
- Bring red pin (or wiggling finger) slowly into view from extreme of your vision, as shown
- Ask patient to say ‘now’ when it comes into view
- Continue to move pin into centre of vision and ask patient to tell you if it disappears
- Repeat in each of four quadrants
- Repeat in other eye

A bitemporal hemianopia is the classical finding in pituitary macroadenomas (p. 683)

6 Examination in Graves' ophthalmopathy

- Inspect from front and side
  - Periorbital oedema (Fig. 18.8)
  - Conjunctival inflammation (chemosis)
  - Corneal ulceration
  - Proptosis (exophthalmos)
  - Lid retraction
- Range of eye movements
  - Lid lag on descending gaze
  - Diplopia on lateral gaze
- Pupillary reflexes
  - Afferent defect (pupils constrict further on swinging light to unaffected eye, Box 25.22)
- Vision
  - Visual acuity impaired
  - Loss of colour vision
  - Visual field defects
- Ophthalmoscopy
  - Optic disc pallor
  - Papilloedema
- *Note position of eyelids relative to iris.

7 Examination of the thyroid gland

- Inspect from front to side
- Palpate from behind
  - Thyroid moves on swallowing
  - Check if lower margin is palpable
  - Cervical lymph nodes
  - Tracheal deviation
- Auscultate for bruit
  - Ask patient to hold breath
  - If present, check for radiating murmur
- Percuss for retrosternal thyroid
- Consider systemic signs of thyroid dysfunction (Box 18.7) incl. tremor, palmar erythema, warm peripheries, tachycardia, lid lag
- Consider signs of Graves' disease incl. ophthalmopathy, pretibial myxoedema
- Check for Pemberton's sign, i.e. facial engorgement when arms raised above head

Abnormal findings

- Diffuse soft goitre with bruit
  - Graves' disease (p. 643)
- Diffuse firm goitre
  - Hashimoto's thyroiditis (p. 646)
- Diffuse tender goitre
  - Subacute thyroiditis (p. 646)
- Multinodular goitre (p. 648)
  - ± Retrosternal extension, tracheal compression
- Solitary nodule (p. 642)
  - Adenoma, cyst or carcinoma
- Cervical lymphadenopathy
  - Suggests carcinoma
Endocrinology concerns the synthesis, secretion and action of hormones. These are chemical messengers released from endocrine glands that coordinate the activities of many different cells. Endocrine diseases can therefore affect multiple organs and systems. This chapter describes the principles of endocrinology before dealing with the function and diseases of each gland in turn.

Some endocrine disorders are common, particularly those of the thyroid, parathyroid glands, reproductive system and β cells of the pancreas (Ch. 20). For example, thyroid dysfunction occurs in more than 10% of the population in areas with iodine deficiency, such as the Himalayas, and 4% of women aged 20–50 years in the UK. Less common endocrine syndromes are described later in the chapter.

Few endocrine therapies have been evaluated by randomised controlled trials, in part because hormone replacement therapy (e.g. with levothyroxine) has obvious clinical benefits and placebo-controlled trials would be unethical. Where trials have been performed, they relate mainly to use of therapy that is ‘optional’ and/or more recently available, such as oestrogen replacement in post-menopausal women, androgen therapy in older men and growth hormone replacement.

### An overview of endocrinology

#### Functional anatomy and physiology

Some endocrine glands, such as the parathyroids and pancreas, respond directly to metabolic signals, but most are controlled by hormones released from the pituitary gland. Anterior pituitary hormone secretion is controlled in turn by substances produced in the hypothalamus and released into portal blood, which drains directly to the pituitary gland (Fig. 18.1). Posterior pituitary hormones are synthesised in the hypothalamus and transported down nerve axons, to be released from the posterior pituitary. Hormone release in the hypothalamus and pituitary is regulated by numerous stimuli and through feedback control by hormones produced by the target glands (thyroid, adrenal cortex and gonads). These integrated endocrine systems are called ‘axes’ and are listed in Figure 18.2.

A wide variety of molecules can act as hormones, including peptides such as insulin and growth hormone, glycoproteins such as thyroid-stimulating hormone, and amines such as noradrenaline (norepinephrine). The biological effects of hormones are mediated by binding to receptors. Many receptors are located on the cell surface. These interact with various intracellular signalling molecules on the cytosolic side of the plasma membrane to affect cell function, usually through changes in gene expression. Some hormones, most notably steroids, triiodothyronine (T3) and vitamin D, bind to specific intracellular receptors. The hormone/receptor complex forms a ligand-activated transcription factor, which regulates gene expression directly (p. 39).

The classical model of endocrine function involves hormones synthesised in endocrine glands, which are released into the circulation and act at sites distant from those of secretion (as in Fig. 18.1). However, additional levels of regulation are now recognised. Many other organs secrete hormones or contribute to the peripheral metabolism and activation of prohormones. A notable example is the production of oestrogens from adrenal androgens in adipose tissue by the enzyme aromatase. Some hormones, such as neurotransmitters, act in a paracrine fashion to affect adjacent cells, or act in an autocrine way to affect behaviour of the cell that produces the hormone.

### Endocrine pathology

For each endocrine axis or major gland, diseases can be classified as shown in Box 18.1. Pathology arising within the gland is often called ‘primary’ disease (e.g. primary hypothyroidism in Hashimoto’s thyroiditis), while abnormal stimulation of the gland is often called ‘secondary’ disease (e.g. secondary hypothyroidism in patients with a pituitary tumour and thyroid-stimulating hormone

---

**Fig. 18.1** An archetypal endocrine axis. Regulation by negative feedback and direct control is shown, along with the equilibrium between active circulating free hormone and bound or metabolised hormone.

deficiency). Some pathological processes can affect multiple endocrine glands (p. 688); these may have a genetic basis (such as organ-specific autoimmune endocrine disorders and the multiple endocrine neoplasia (MEN) syndromes) or be a consequence of therapy for another disease (e.g. following treatment of childhood cancer with chemotherapy and/or radiotherapy).

Investigation of endocrine disease

Biochemical investigations play a central role in endocrinology. Most hormones can be measured in blood but the circumstances in which the sample is taken are often crucial, especially for hormones with pulsatil secretory reaction, such as growth hormone; those that show diurnal variation, such as cortisol; or those that demonstrate monthly variation, such as oestradiol or progesterone. Some hormones are labile and need special collection, handling and processing requirements, e.g. collection in a special tube and/or rapid transportation to the laboratory on ice. Local protocols for hormone measurement should be carefully followed. Other investigations, such as imaging and biopsy, are more frequently reserved for patients who present with a tumour. The principles of investigation are shown in Box 18.2. The choice of test is often pragmatic, taking local access to reliable sampling facilities and laboratory measurements into account.

Presenting problems in endocrine disease

Endocrine diseases present in many different ways and to clinicians in many different disciplines. Classical syndromes are described in relation to individual glands in the following sections. Often, however, the presentation is with non-specific symptoms (Box 18.3) or with asymptomatic biochemical abnormalities. In

![Diagram of the endocrine system](image-url)

**Fig. 18.2** The principal endocrine ‘axes’. Some major endocrine glands are not controlled by the pituitary. These include the parathyroid glands (regulated by calcium concentrations, p. 661), the adrenal zona glomerulosa (regulated by the renin–angiotensin system, p. 665) and the endocrine pancreas (Ch. 20). Italics show negative regulation. (ACTH = adrenocorticotrophic hormone; CRH = corticotrophin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GnRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; IGF-1 = insulin-like growth factor-1; IGF-BP3 = IGF-binding protein-3; LH = luteinising hormone; T3 = triiodothyronine; T4 = thyroxine; TRH = thyrotrophin-releasing hormone; TSH = thyroid-stimulating hormone; vasopressin = antidiuretic hormone (ADH)).

**18.2 Principles of endocrine investigation**

**Timing of measurement**
- Release of many hormones is rhythmic (pulsatile, circadian or monthly), so random measurement may be invalid and sequential or dynamic tests may be required

**Choice of dynamic biochemical test**
- Abnormalities are often characterised by loss of normal regulation of hormone secretion
- If hormone deficiency is suspected, choose a stimulation test
- If hormone excess is suspected, choose a suppression test
- The more tests there are to choose from, the less likely it is that any single test is infallible, so avoid interpreting one result in isolation

**Imaging**
- ‘Functional’ as well as conventional ‘structural’ imaging can be performed as secretory endocrine cells can also take up labelled substrates, e.g. radio-labelled iodine or octreotide
- Most endocrine glands have a high prevalence of ‘incidentalomas’, so do not scan unless the biochemistry confirms endocrine dysfunction or the primary problem is a tumour

**Biopsy**
- Many endocrine tumours are difficult to classify histologically (e.g. adrenal carcinoma and adenoma)

In addition, endocrine diseases are encountered in the differential diagnosis of common complaints discussed in other chapters of this book, including electrolyte abnormalities (Ch. 14), hypertension (Ch. 16), obesity (Ch. 19) and osteoporosis (Ch. 24). Although diseases of the adrenal glands, hypothalamus and pituitary are relatively rare, their diagnosis often relies on astute clinical observation in a patient with non-specific complaints, so it is important that clinicians are familiar with their key features.

### The thyroid gland

Diseases of the thyroid, summarised in Box 18.4, predominantly affect females and are common, occurring in about 5% of the population. The thyroid axis is involved in the regulation of cellular differentiation and metabolism in virtually all nucleated cells, so that disorders of thyroid function have diverse manifestations. Structural diseases of the thyroid gland, such as goitre, commonly occur in patients with normal thyroid function.

#### Functional anatomy, physiology and investigations

Thyroid physiology is illustrated in Figure 18.3. The parafollicular C cells secrete calcitonin, which is of no apparent physiological significance in humans. The follicular epithelial cells synthesise thyroid hormones by incorporating iodine into the amino acid tyrosine on the surface of thyroglobulin (Tg), a protein secreted into the colloid of the follicle. Iodide is a key substrate for thyroid hormone synthesis; a dietary intake in excess of 100 μg/day is required to maintain thyroid function in adults. The thyroid secretes predominantly thyroxyrin (T3) and only a small amount of triiodothyronine (T4); approximately 85% of T4 is produced from T3 by a family of monodeiodinase enzymes that are active in many tissues, including liver, muscle, heart and kidney. Selenium is an integral component of these monodeiodinases. T3 can be regarded as a prohormone, since it has a longer half-life in blood than T4 (approximately 1 week compared with approximately 18 hours), and binds and activates thyroid hormone receptors less effectively than T4. T3 can also be converted to the inactive metabolite, reverse T3.

T3 and T4 circulate in plasma almost entirely (>99%) bound to transport proteins, mainly thyroxine-binding globulin (TBG). It is the unbound or free hormones that diffuse into tissues and exert diverse metabolic actions. Some laboratories use assays that measure total T4 and T3 in plasma but it is increasingly common to measure free T4 and free T3. The theoretical advantage of the free hormone measurements is that they are not influenced by changes in the concentration of binding proteins. For example, TBG levels are increased by oestrogen (such as in the combined oral contraceptive pill) and this will result in raised total T3 and T4, although free thyroid hormone levels are normal.

Production of T3 and T4 in the thyroid is stimulated by thyrotrophin (thyroid-stimulating hormone, TSH), a glycoprotein released from the thyrotroph cells of the anterior pituitary in response to the hypothalamic tripeptide, thyrotrophin-releasing hormone (TRH). A circadian rhythm of TSH secretion can be demonstrated with a peak at 0100 hrs and trough at 1100 hrs, but the variation is small so that thyroid function can be assessed reliably from a single blood sample taken at any time of day and does not usually require any dynamic stimulation or suppression tests. There is a negative feedback of thyroid hormones on the hypothalamus and pituitary such that in thyrotoxicosis, when plasma concentrations of T3 and T4 are raised, TSH secretion is suppressed. Conversely, in hypothyroidism due to disease of the thyroid gland, low T3 and T4 are associated with high circulating TSH levels. The relationship between TSH and T4 is classically described as inverse log-linear (Fig. 18.4). The anterior pituitary is, though, very sensitive to minor changes in thyroid hormone levels within the reference range. For example, in an individual whose free T4 level is usually 15 pmol/L (1.17 ng/dL), a rise or fall of 5 pmol/L (0.39 ng/dL) would be associated on the one hand with undetectable TSH, and on the other hand with a raised TSH. For this reason, TSH is usually regarded as the most useful investigation of thyroid function. However, interpretation of TSH values without considering thyroid hormone levels may be misleading in patients with pituitary disease; for example, TSH is inappropriately low or ‘normal’ in secondary hypothyroidism (see Box 18.5 and Box 18.53, p. 680). Moreover, TSH may take several weeks to ‘catch up’ with T4 and T3 levels; for example, levothyroxine therapy will raise T4 and T3 levels within approximately 2 weeks but it may take 4–6 weeks for the TSH to reach a steady state. Heterophilic antibodies (host antibodies with affinity to the animal antibodies used in biological assays, p. 242) can also interfere with the TSH assay and cause a spuriously high or low measurement. Common patterns of abnormal thyroid function test results and their interpretation are shown in Box 18.5.

Other modalities commonly employed in the investigation of thyroid disease include measurement of antibodies against...
The thyroid gland

•  The most common presentations are hyperthyroidism (thyrotoxicosis), hypothyroidism and enlargement of the thyroid (goitre or thyroid nodule). Widespread availability of thyroid function tests has led to the increasingly frequent identification of patients with abnormal results who either are asymptomatic or have non-specific complaints such as tiredness and weight gain.

Presenting problems in thyroid disease

The most common presentations are hyperthyroidism (thyrotoxicosis), hypothyroidism and enlargement of the thyroid (goitre or thyroid nodule). Widespread availability of thyroid function tests has led to the increasingly frequent identification of patients with abnormal results who either are asymptomatic or have non-specific complaints such as tiredness and weight gain.

Thyrotoxicosis

Thyrotoxicosis describes a constellation of clinical features arising from elevated circulating levels of thyroid hormone. The most common causes are Graves’ disease, multinodular goitre and autonomously functioning thyroid nodules (toxic adenoma) (Box 18.6). Thyroiditis is more common in parts of the world where relevant viral infections occur, such as North America.

Clinical assessment

The clinical manifestations of thyrotoxicosis are shown in Box 18.7 and an approach to differential diagnosis is given in
Figure 18.5. The most common symptoms are weight loss with a normal or increased appetite, heat intolerance, palpitations, tremor and irritability. Tachycardia, palmar erythema and lid lag are common signs. Not all patients have a palpable goitre, but experienced clinicians can discriminate the diffuse soft goitre of Graves’ disease from the irregular enlargement of a multinodular goitre. All causes of thyrotoxicosis can cause lid retraction and lid lag, due to potentiation of sympathetic innervation of the levator palpabrae muscles, but only Graves’ disease causes other features of ophthalmopathy, including periorbital oedema, conjunctival irritation, exophthalmos and diplopia. Pretibial myxoedema (p. 646) and the rare thyroid acropachy (a periosteal hypertrophy, indistinguishable from finger clubbing) are also specific to Graves’ disease.

Investigations

The first-line investigations are serum T₃, T₄ and TSH. If abnormal values are found, the tests should be repeated and the abnormality confirmed in view of the likely need for prolonged medical treatment or destructive therapy. In most patients, serum T₃ and T₄ are both elevated, but T₄ is in the upper part of the reference range and T₃ is raised (T₃ toxicosis) in about 5%. Serum TSH is undetectable in primary thyrotoxicosis, but values can be raised in the very rare syndrome of secondary thyrotoxicosis caused by a TSH-producing pituitary adenoma. When biochemical thyrotoxicosis has been confirmed, further investigations should be undertaken to determine the underlying cause, including measurement of TSH receptor antibodies (TRAb, elevated in Graves’ disease; Box 18.8) and radiotrace scanning, as shown in Figure 18.5. Other non-specific abnormalities are common

1 Thyroid peroxidase (TPO) antibodies are the principal component of what was previously measured as thyroid 'microsomal' antibodies. 2 Thyroid-stimulating hormone receptor antibodies (TRAb) can be agonists (stimulatory, causing Graves' thyrotoxicosis) or antagonists ('blocking', causing hypothyroidism).

(Box 18.9). An electrocardiogram (ECG) may demonstrate sinus tachycardia or atrial fibrillation.

Radio-iodine uptake tests measure the proportion of isotope that is trapped in the whole gland but have been largely superseded by technetium scintigraphy scans, which also indicate trapping, are quicker to perform with a lower dose of radioactivity, and provide a higher-resolution image. In low-uptake thyrotoxicosis, the cause is usually a transient thyroiditis (p. 646). Occasionally, patients induce 'factitious thyrotoxicosis' by consuming excessive amounts of a thyroid hormone preparation, most often levothyroxine. The exogenous levothyroxine suppresses pituitary TSH secretion and hence iodine uptake, serum thyroglobulin and release of endogenous thyroid hormones. The T₄:T₃ ratio (typically 30:1 in conventional thyrotoxicosis) is increased to above 70:1 because circulating T₃ in factitious thyrotoxicosis is derived exclusively from the peripheral monodeiodination of T₄ and not from thyroid secretion. The combination of negligible iodine uptake, high T₄:T₃ ratio and a low or undetectable thyroglobulin is diagnostic.

**Management**

Definitive treatment of thyrotoxicosis depends on the underlying cause and may include antithyroid drugs, radioactive iodine or surgery. A non-selective β-adrenoceptor antagonist (β-blocker), such as propranolol (160 mg daily) or nadolol (40–80 mg daily), will alleviate but not abolish symptoms in most patients within 24–48 hours. Beta-blockers should not be used for long-term...
Fig. 18.5 Establishing the differential diagnosis in thyrotoxicosis. 1Graves’ ophthalmopathy refers to clinical features of exophthalmos and periorbital and conjunctival oedema, not simply the lid lag and lid retraction that can occur in all forms of thyrotoxicosis. 2Thyroid-stimulating hormone (TSH) receptor antibodies are very rare in patients without autoimmune thyroid disease but occur in only 80–95% of patients with Graves’ disease; a positive test is therefore confirmatory but a negative test does not exclude Graves’ disease. Other thyroid antibodies (e.g. anti-peroxidase and anti-thyroglobulin antibodies) are unhelpful in the differential diagnosis since they occur frequently in the population and are found with several of the disorders that cause thyrotoxicosis. 3Scintigraphy is not necessary in most cases of drug-induced thyrotoxicosis. 4 99mTechnetium pertechnetate scans of patients with thyrotoxicosis. In low-uptake thyrotoxicosis, most commonly due to a viral, post-partum or iodine-induced thyroiditis, there is negligible isotope detected in the region of the thyroid, although uptake is apparent in nearby salivary glands (not shown here). In a toxic adenoma there is lack of uptake of isotope by the rest of the thyroid gland due to suppression of serum TSH. In multinodular goitre there is relatively low, patchy uptake within the nodules; such an appearance is not always associated with a palpable thyroid. In Graves’ disease there is diffuse uptake of isotope.

18.9 Non-specific laboratory abnormalities in thyroid dysfunction

Thyrotoxicosis
- Serum enzymes: raised alanine aminotransferase, γ-glutamyl transferase (GGT), and alkaline phosphatase from liver and bone
- Raised bilirubin
- Mild hypercalcaemia
- Glycosuria: associated diabetes mellitus, ‘lag storage’ glycosuria

Hypothyroidism
- Serum enzymes: raised creatine kinase, aspartate aminotransferase, lactate dehydrogenase (LDH)
- Hypercholesterolaemia
- Anaemia: normochromic normocytic or macrocytic
- Hyponatraemia

*These abnormalities are not useful in differential diagnosis, so the tests should be avoided and any further investigation undertaken only if abnormalities persist when the patient is euthyroid.

Treatment of thyrotoxicosis but are extremely useful in the short term, while patients are awaiting hospital consultation or following 131I therapy. Verapamil may be used as an alternative to β-blockers, e.g. in patients with asthma, but usually is only effective in improving tachycardia and has little effect on the other systemic manifestations of thyrotoxicosis.

Atrial fibrillation in thyrotoxicosis

Atrial fibrillation occurs in about 10% of patients with thyrotoxicosis. The incidence increases with age, so that almost half of all males with thyrotoxicosis over the age of 60 are affected. Moreover, subclinical thyrotoxicosis (p. 642) is a risk factor for atrial fibrillation. Characteristically, the ventricular rate is little influenced by digoxin but responds to the addition of a β-blocker. Thromboembolic vascular complications are particularly common in thyrotoxic atrial fibrillation so that anticoagulation is required, unless contraindicated. Once thyroid hormone and TSH concentrations have been returned to normal, atrial fibrillation will spontaneously revert to sinus rhythm in about 50% of patients but cardioversion may be required in the remainder.
Thyroid gland

- 639 18

hormones but also reduces the conversion of T4 to T3, and is therefore more effective than potassium iodide or Lugol’s solution. Dexamethasone (2 mg 4 times daily) and amiodarone have similar effects. Oral carbimazole 40–60 mg daily (p. 644) should be given to inhibit the synthesis of new thyroid hormone. If the patient is unconscious or uncooperative, carbimazole can be administered rectally with good effect but no preparation is available for parenteral use. After 10–14 days the patient can usually be maintained on carbimazole alone.

Hypothyroidism

Hypothyroidism is a common condition with various causes (Box 18.11), but autoimmune disease (Hashimoto’s thyroiditis) and thyroid failure following 131I or surgical treatment of thyrotoxicosis account for over 90% of cases, except in areas where iodine deficiency is endemic. Women are affected approximately six times more frequently than men.

Clinical assessment

The clinical presentation depends on the duration and severity of the hypothyroidism. Those in whom complete thyroid failure has developed insidiously over months or years may present with many of the clinical features listed in Box 18.7. A consequence of prolonged hypothyroidism is the infiltration of many body tissues by the mucopolysaccharides hyaluronic acid and chondroitin.

Thyrotoxic crisis (‘thyroid storm’)

This is a rare but life-threatening complication of thyrotoxicosis. The most prominent signs are fever, agitation, delirium, tachycardia or atrial fibrillation and, in the older patient, cardiac failure. The Burch–Wartofsky system may be used to help establish the diagnosis (Box 18.10). Thyrotoxic crisis is a medical emergency and has a mortality of 10% despite early recognition and treatment. It is most commonly precipitated by infection in a patient with previously unrecognised or inadequately treated thyrotoxicosis. It may also develop in known thyrotoxicosis shortly after thyroidectomy in an ill-prepared patient or within a few days of 131I therapy, when acute radiation damage may lead to a transient rise in serum thyroid hormone levels.

Patients should be rehydrated and given propranolol, either orally (80 mg 4 times daily) or intravenously (1–5 mg 4 times daily). Sodium ipodate (500 mg per day orally) will restore serum T3 levels to normal in 48–72 hours. This is a radiographic contrast medium that not only inhibits the release of thyroid hormones but also reduces the conversion of T4 to T3, and is therefore more effective than potassium iodide or Lugol’s solution. Dexamethasone (2 mg 4 times daily) and amiodarone have similar effects. Oral carbimazole 40–60 mg daily (p. 644) should be given to inhibit the synthesis of new thyroid hormone. If the patient is unconscious or uncooperative, carbimazole can be administered rectally with good effect but no preparation is available for parenteral use. After 10–14 days the patient can usually be maintained on carbimazole alone.

Hypothyroidism

Hypothyroidism is a common condition with various causes (Box 18.11), but autoimmune disease (Hashimoto’s thyroiditis) and thyroid failure following 131I or surgical treatment of thyrotoxicosis account for over 90% of cases, except in areas where iodine deficiency is endemic. Women are affected approximately six times more frequently than men.

Clinical assessment

The clinical presentation depends on the duration and severity of the hypothyroidism. Those in whom complete thyroid failure has developed insidiously over months or years may present with many of the clinical features listed in Box 18.7. A consequence of prolonged hypothyroidism is the infiltration of many body tissues by the mucopolysaccharides hyaluronic acid and chondroitin.

1 As shown in Box 18.8, thyroid autoantibodies are common in the healthy population, so might be present in anyone. ++ high titre; + more likely to be detected than in the healthy population; – not especially likely. 2 Goitre: – absent; ± may be present; ++ characteristic. (TPO = thyroid peroxidase; TSH = thyroid-stimulating hormone)
childhood. Immunoreactive thyroid-stimulating hormone (TSH) may be detected at normal or even modestly elevated levels in patients with pituitary failure; such as thyroid aplasia and dyshormonogenesis (associated with nerve deafness in Pendred’s syndrome, p. 650), which are usually diagnosed in patients with transient hypothyroidism. Levothyroxine treatment is not always necessary, as the patient needs to be maintained so that the diagnosis is not overlooked since they do not discriminate reliably between euthyroidism and hypothyroidism. Secondary hypothyroidism is rare, but is suggested by deficiency of pituitary hormones or by clinical features of pituitary tumour such as headache or visual field defect (p. 683). Rare causes of hypothyroidism with goitre include dyshormonogenesis and infiltration of the thyroid (see Box 18.11).

In this situation, serum T4 is low and TSH is elevated, usually in excess of 20 mIU/L. Measurements of serum T3 are unhelpful since they do not discriminate reliably between euthyroidism and hypothyroidism. Secondary hypothyroidism is rare and is caused by failure of TSH secretion in an individual with hypothalamic or anterior pituitary disease. Other non-specific abnormalities are shown in Box 18.9. In severe, prolonged hypothyroidism, the ECG classically demonstrates sinus bradycardia with low-voltage complexes and ST-segment and T-wave abnormalities. Measurement of thyroid peroxidase antibodies is helpful but further investigations are rarely required (Fig. 18.6).

Management

Treatment is with levothyroxine replacement. It is customary to start with a low dose of 50 μg per day for 3 weeks, increasing thereafter to 100 μg per day for a further 3 weeks and finally to a maintenance dose of 100–150 μg per day. In younger patients, it is safe to initiate levothyroxine at a higher dose (e.g. 100 μg per day), to allow a more rapid normalisation of thyroid hormone levels. Levothyroxine has a half-life of 7 days so it should always be taken as a single daily dose and at least 6 weeks should pass before repeating thyroid function tests (as TSH takes several weeks to reach a steady state) and adjusting the dose. Patients feel better within 2–3 weeks. Reduction in weight and peribital puffiness occurs quickly but the restoration of skin and hair texture and resolution of any effusions may take 3–6 months. As illustrated in Figure 18.6, most patients do not require specialist review but will need life-long levothyroxine therapy.

The dose of levothyroxine should be adjusted to maintain serum TSH within the reference range. To achieve this, serum T4 often needs to be in the upper part of the reference range because the T4 required for receptor activation is derived exclusively from conversion of T3 within the target tissues, without the usual contribution from thyroid secretion. Some physicians advocate

**Fig. 18.6 An approach to adults with suspected primary hypothyroidism.** This scheme ignores congenital causes of hypothyroidism (see Box 18.11), such as thyroid aplasia and dyshormonogenesis (associated with nerve deafness in Pendred’s syndrome, p. 650), which are usually diagnosed in childhood. Immunoreactive thyroid-stimulating hormone (TSH) may be detected at normal or even modestly elevated levels in patients with pituitary failure; unless T4 is only marginally low, TSH should be >20 mIU/L to confirm the diagnosis of primary hypothyroidism. The usual abnormality in sick euthyroidism is a low TSH but any pattern can occur. Thyroid peroxidase (TPO) antibodies are highly sensitive but not very specific for autoimmune thyroid disease (see Boxes 18.8 and 18.11). Specialist advice is most appropriate where indicated. Secondary hypothyroidism is rare, but is suggested by deficiency of pituitary hormones or by clinical features of pituitary tumour such as headache or visual field defect (p. 683). Rare causes of hypothyroidism with goitre include dyshormonogenesis and infiltration of the thyroid (see Box 18.11).
combined replacement with T₄ (levothyroxine) and T₃ (liothyronine) or preparations of animal thyroid extract but this approach remains controversial and is not supported by robust evidence. Some patients remain symptomatic despite normalisation of TSH and may wish to take extra levothyroxine, which suppresses TSH. However, suppressed TSH is a risk factor for osteoporosis and atrial fibrillation (see below; subclinical thyrotoxicosis), so this approach cannot be recommended.

It is important to measure thyroid function every 1–2 years once the dose of levothyroxine is stabilised. This encourages adherence to therapy and allows adjustment for variable underlying thyroid activity and other changes in levothyroxine requirements (Box 18.12). Some patients have a persistent elevation of serum TSH despite an ostensibly adequate replacement dose of levothyroxine; most commonly, this is a consequence of suboptimal adherence to therapy. There may be differences in bioavailability between the numerous generic preparations of levothyroxine and so, if an individual is experiencing marked changes in serum TSH despite optimal adherence, the prescription of a branded preparation of levothyroxine could be considered. There is some limited evidence that suggests levothyroxine absorption may be better when the drug is taken before bed and can be further optimised by adding a vitamin C supplement; such strategies may be considered in patients with malabsorption. In some poorly compliant patients, levothyroxine is taken diligently or even in excess for a few days prior to a clinic visit, resulting in the seemingly anomalous combination of a high serum T₄ and high TSH (see Box 18.5).

Levothyroxine replacement in ischaemic heart disease

Hypothyroidism and ischaemic heart disease are common conditions that often occur together. Although angina may remain unchanged in severity or paradoxically disappear with restoration of metabolic rate, exacerbation of myocardial ischaemia, infarction and sudden death are recognised complications of levothyroxine replacement, even using doses as low as 25 μg per day. In patients with known ischaemic heart disease, thyroid hormone replacement should be introduced at low dose and increased very slowly under specialist supervision. It has been suggested that T₄ has an advantage over T₃, since T₃ has a shorter half-life and any adverse effect will reverse more quickly, but the more distinct peak in hormone levels after each dose of T₄ is a disadvantage. Coronary intervention may be required if angina is exacerbated by levothyroxine replacement therapy.

Hypothyroidism in pregnancy

Women with hypothyroidism usually require an increased dose of levothyroxine in pregnancy; inadequately treated hypothyroidism in pregnancy has been associated with impaired cognitive development in the fetus. This is discussed in more detail on page 1279 (see also Box 18.18).

Myxoedema coma

This is a very rare presentation of hypothyroidism in which there is a depressed level of consciousness, usually in an elderly patient who appears myxoedematous. Body temperature may be as low as 25°C, convulsions are not uncommon, and cerebrospinal fluid (CSF) pressure and protein content are raised. The mortality rate is 50% and survival depends on early recognition and treatment of hypothyroidism and other factors contributing to the altered consciousness level, such as medication, cardiac failure, pneumonia, dilutional hyponatraemia and respiratory failure.

Myxoedema coma is a medical emergency and treatment must begin before biochemical confirmation of the diagnosis. Suspected cases should be treated with an intravenous injection of 20 μg liothyronine, followed by further injections of 20 μg 3 times daily until there is sustained clinical improvement. In survivors, there is a rise in body temperature within 24 hours and, after 48–72 hours, it is usually possible to switch patients to oral levothyroxine in a dose of 50 μg daily. Unless it is apparent that the patient has primary hypothyroidism, the thyroid failure should also be assumed to be secondary to hypothalamic or pituitary disease and treatment given with hydrocortisone 100 mg IM 3 times daily, pending the results of T₄, TSH and cortisol measurement (p. 680). Other measures include slow rewarming (p. 166), cautious use of intravenous fluids, broad-spectrum antibiotics and high-flow oxygen.

Symptoms of hypothyroidism with normal thyroid function tests

The classic symptoms of hypothyroidism are, by their very nature, non-specific (see Box 18.3). There is a wide differential diagnosis for symptoms such as ‘fatigue’, ‘weight gain’ and ‘low mood’. As has been noted, outside the context of pituitary and hypothalamic disease, serum TSH is an excellent measure of an individual’s thyroid hormone status. However, some individuals believe that they have hypothyroidism despite normal serum TSH concentrations. There are a large number of websites that claim that serum TSH is not a good measure of thyroid hormone status and suggest that other factors, such as abnormalities of T₄ to T₃ conversion, may lead to low tissue levels of active thyroid hormones. Such websites often advocate a variety of tests of thyroid function of dubious scientific validity, including measurement of serum reverse T₃, 24-hour urine T₄, basal body temperature, skin iodine absorption, and levels of selenium in blood and urine. Individuals who believe they have hypothyroidism, despite normal conventional tests of thyroid function, can be difficult to manage. They require reassurance that their symptoms are being taken seriously and that organic disease has been carefully considered; if their symptoms persist, referral to a
and require therapy, usually with $^{131}$I. Otherwise, annual review hence the consensus view is that they have mild thyrotoxicosis and are at increased risk of atrial fibrillation and osteoporosis, and found in older patients with multinodular goitre. These patients are at increased risk of atrial fibrillation and osteoporosis, and hence the consensus view is that they have mild thyrotoxicosis and require therapy, usually with $^{131}$I. Otherwise, annual review is essential, as the conversion rate to overt thyrotoxicosis with elevated T$_2$ and/or T$_3$ concentrations is 5% each year.

**Subclinical hypothyroidism**

Serum TSH is raised and serum T$_3$ and T$_4$ concentrations are at the lower end of the reference range. This may persist for many years, although there is a risk of progression to overt thyroid failure, particularly if antibodies to thyroid peroxidase are present or if the TSH rises above 10 mIU/L. In patients with non-specific symptoms, a trial of levothyroxine therapy may be appropriate. In those with positive autoantibodies or a TSH greater than 10 mIU/L, it is better to treat the thyroid failure early rather than risk loss to follow-up and subsequent presentation with profound hypothyroidism. Levothyroxine should be given in a dose sufficient to restore the serum TSH concentration to normal.

**Non-thyroidal illness (‘sick euthyroidism’)**

This typically presents with a low serum TSH, raised T$_4$ and normal or low T$_3$ in a patient with systemic illness who does not have clinical evidence of thyroid disease. These abnormalities are caused by decreased peripheral conversion of T$_4$ to T$_3$ (with conversion instead to reverse T$_3$), altered levels of binding proteins and their affinity for thyroid hormones, and often reduced secretion of TSH. During convalescence, serum TSH concentrations may increase to levels found in primary hypothyroidism. As thyroid function tests are difficult to interpret in patients with non-thyroidal illness, it is wise to avoid performing thyroid function tests unless there is clinical evidence of concomitant thyroid disease. If an abnormal result is found, treatment should only be given with specialist advice and the diagnosis should be re-evaluated after recovery.

**Thyroid lump or swelling**

A lump or swelling in the thyroid gland can be a source of considerable anxiety for patients. There are numerous causes but, broadly speaking, a thyroid swelling is either a solitary nodule, a multinodular goitre or a diffuse goitre (Box 18.13). Nodular thyroid disease is more common in women and occurs in approximately 30% of the adult female population. The majority of thyroid nodules are impalpable but may be identified when imaging of the neck is performed for another reason, such as during Doppler ultrasonography of the carotid arteries or computed tomographic pulmonary angiography. Increasingly, thyroid nodules are identified during staging of patients with cancer with computed tomography (CT), magnetic resonance imaging (MRI) or positron emission tomography (PET) scans. Palpable thyroid nodules occur in 4–8% of adult women and 1–2% of adult men, and classically present when the individual (or a friend or relative) notices a lump in the neck. Multinodular goitre and solitary nodules sometimes present with acute painful enlargement due to haemorrhage into a nodule.

Patients with thyroid nodules often worry that they have cancer but the reality is that only 5–10% of thyroid nodules are malignant. A nodule presenting in childhood or adolescence, particularly if there is a past history of head and neck irradiation, or one presenting in an elderly patient should heighten suspicion of a primary thyroid malignancy (p. 649). The presence of cervical lymphadenopathy also increases the likelihood of malignancy. Rarely, a secondary deposit from a renal, breast or lung carcinoma presents as a painful, rapidly growing, solitary thyroid nodule. Thyroid nodules identified on PET scanning have an approximately 33% chance of being malignant.

**Clinical assessment and investigations**

Swellings in the anterior part of the neck most commonly originate in the thyroid and this can be confirmed by demonstrating that the swelling moves on swallowing (p. 631). It is often possible to distinguish clinically between the three main causes of thyroid swelling. There is a broad differential diagnosis of anterior neck swellings, which includes lymphadenopathy, branchial cysts, dermoid cysts and thyroglossal duct cysts (the latter are classically located in the midline and move on protrusion of the tongue). An ultrasound scan should be performed urgently, if there is any doubt as to the aetiology of an anterior neck swelling.

Serum T$_3$, T$_4$ and TSH should be measured in all patients with a goitre or solitary thyroid nodule. The finding of biochemical thyrotoxicosis or hypothyroidism (both of which may be subclinical) should lead to investigations, as already described on pages 636 and 640.

**Thyroid scintigraphy**

Thyroid scintigraphy with $^{99m}$technetium should be performed in an individual with a low serum TSH and a nodular thyroid to confirm the presence of an autonomously functioning (‘hot’) nodule (see Fig. 18.5). In such circumstances, further evaluation is not necessary. ‘Cold’ nodules on scintigraphy have a much higher likelihood of malignancy, but the majority are benign and so scintigraphy is not routinely used in the evaluation of thyroid nodules when TSH is normal.
Thyroid ultrasound

If thyroid function tests are normal, an ultrasound scan will often determine the nature of the thyroid swelling. Ultrasound can establish whether there is generalised or localised swelling of the thyroid. Inflammatory disorders causing a diffuse goitre, such as Graves’ disease and Hashimoto’s thyroiditis, demonstrate a diffuse pattern of hypoechogenicity and, in the case of Graves’ disease, increased thyroid blood flow may be seen on colour-flow Doppler. The presence of thyroid autoantibodies will support the diagnosis of Graves’ disease or Hashimoto’s thyroiditis, while their absence in a younger patient with a diffuse goitre and normal thyroid function suggests a diagnosis of ‘simple goitre’ (p. 648).

Ultrasound can readily determine the size and number of nodules within the thyroid and can distinguish solid nodules from those with a cystic element. Ultrasound is used increasingly as the key investigation in defining the risk of malignancy in a nodule. Size of the nodule is not a predictor of the risk of malignancy but there are other ultrasound characteristics that are associated with a higher likelihood of malignancy. These include hypoechogenicity, intranodular vascularity, the presence of microcalcification and irregular or lobulated margins. A purely cystic nodule is highly unlikely to be malignant and a ‘spongiform’ appearance is also highly predictive of a benign aetiology. Individual nodules within a multinodular goitre have the same risk of malignancy as a solitary nodule. Thyroid ultrasonography is a highly specialised investigation and the accurate stratification of risk of malignancy of a thyroid nodule requires skill and expertise.

Fine needle aspiration cytology

Fine needle aspiration cytology is recommended for thyroid nodules that are suspicious for malignancy or are radiologically indeterminate. Fine needle aspiration of a thyroid nodule can be performed in the outpatient clinic, usually under ultrasound guidance. Aspiration may be therapeutic for a cyst, although recurrence on more than one occasion is an indication for surgery. Fine needle aspiration cytology cannot differentiate between a follicular adenoma and a follicular carcinoma, and in 10–20% of cases an inadequate specimen is obtained.

Management

Nodules with a benign appearance on ultrasound may be observed in an ultrasound surveillance programme; when the suspicion of malignancy is very low, the patient may be reassured and discharged. In parts of the world with borderline low iodine intake, there is evidence that levothyroxine therapy, in doses that suppress serum TSH, may reduce the size of some nodules. This should not be routine practice in iodine-sufficient populations.

Nodules that are suspicious for malignancy are treated by surgical excision, by either lobectomy or thyroidectomy. Nodules that are radiologically and/or cytologically indeterminate are more of a management challenge and often end up being surgically excised. Molecular techniques may, in the future, improve the diagnostic accuracy of thyroid cytology and allow a more conservative strategy for individuals with an indeterminate biopsy. Nodules in which malignancy is confirmed by formal histology are treated as described on page 649.

A diffuse or multinodular goitre may also require surgical treatment for cosmetic reasons or if there is compression of local structures (resulting in stridor or dysphagia). ¹³¹I therapy may also cause some reduction in size of a multinodular goitre. Levothyroxine therapy may shrink the goitre of Hashimoto’s disease, particularly if serum TSH is elevated.

Autoimmune thyroid disease

Thyroid diseases are amongst the most prevalent antibody-mediated autoimmune diseases and are associated with other organ-specific autoimmunity (Ch. 4 and p. 689). Autoantibodies may produce inflammation and destruction of thyroid tissue, resulting in hypothyroidism, goitre (in Hashimoto’s thyroiditis) or sometimes even transient thyrotoxicosis (‘Hashitoxicosis’), or they may stimulate the TSH receptor to cause thyrotoxicosis (in Graves’ disease). There is overlap between these conditions, since some patients have multiple autoantibodies.

Graves’ disease

Graves’ disease can occur at any age but is unusual before puberty and most commonly affects women aged 30–50 years. The most common manifestation is thyrotoxicosis with or without a diffuse goitre. The clinical features and differential diagnosis are described on page 635. Graves’ disease also causes ophthalmopathy and, rarely, pretibial myxoedema (p. 646). These extrathyroidal features usually occur in thyrotoxic patients but can arise in the absence of thyroid dysfunction.

Graves’ thyrotoxicosis

Pathophysiology

The thyrotoxicosis results from the production of immunoglobulin G (IgG) antibodies directed against the TSH receptor on the thyroid follicular cell, which stimulate thyroid hormone production and proliferation of follicular cells, leading to goitre in the majority of patients. These antibodies are termed thyroid-stimulating immunoglobulins or TSH receptor antibodies (TRAb) and can be detected in the serum of 80–95% of patients with Graves’ disease. The concentration of TRAb in the serum is presumed to fluctuate to account for the natural history of Graves’ thyrotoxicosis (Fig. 18.7). Thyroid failure seen in some patients may result from the presence of blocking antibodies against the TSH receptor, and from tissue destruction by cytotoxic antibodies and cell-mediated immunity.

**Fig. 18.7** Natural history of the thyrotoxicosis of Graves’ disease.

- **A** and **B** The majority (80%) of patients have either prolonged periods of thyrotoxicosis of fluctuating severity, or periods of alternating relapse and remission. **C** It is the minority who experience a single short-lived episode followed by prolonged remission and, in some cases, by the eventual onset of hypothyroidism.
Graves’ disease has a strong genetic component. There is 50% concordance for thyrotoxicosis between monozygotic twins but only 5% concordance between dizygotic twins. Genome-wide association studies have identified polymorphisms at the MHC, CTLA4, PTPN22, TSHR1 and FCRL3 loci as predisposing genetic variants. Many of these loci have been implicated in the pathogenesis of other autoimmune diseases.

A suggested trigger for the development of thyrotoxicosis in genetically susceptible individuals may be infection with viruses or bacteria. Certain strains of the gut organisms Escherichia coli and Yersinia enterocolitica possess cell membrane TSH receptors and it has been suggested that antibodies to these microbial antigens may cross-react with the TSH receptors on the host thyroid follicular cell. In regions of iodine deficiency (p. 647), iodine supplementation can precipitate thyrotoxicosis, but only in those with pre-existing subclinical Graves’ disease. Smoking is weakly associated with Graves’ thyrotoxicosis but strongly linked with the development of ophthalmopathy.

Management

Symptoms of thyrotoxicosis respond to β-blockade (p. 637) but definitive treatment requires control of thyroid hormone secretion. The different options are compared in Box 18.14. Some clinicians adopt an empirical approach of prescribing a course of antithyroid drug therapy and then recommending 131I or surgery if relapse occurs. In many centres, however, 131I is used extensively as a first-line therapy, given the high risk of relapse following a course of antithyroid drugs. A number of observational studies have linked therapeutic 131I with increased incidence of some malignancies, particularly of the thyroid and gastrointestinal tract, but the results have been inconsistent; the association may be with Graves’ disease rather than its therapy, and the magnitude of the effect, if any, is small. Experience from the disaster at the Chernobyl nuclear power plant in 1986 suggests that younger people are more sensitive to radiation-induced thyroid cancer.

**Antithyroid drugs** The most commonly used are carbimazole and its active metabolite, methimazole (not available in the UK). Propylthiouracil is equally effective. These drugs reduce the synthesis of new thyroid hormones by inhibiting the iodination of tyrosine (see Fig. 18.3). Carbimazole also has an immunosuppressive action, leading to a reduction in serum TRAb concentrations, but this is not enough to influence the natural history of the thyrotoxicosis significantly.

Antithyroid drugs should be introduced at high doses (carbimazole 40–60 mg daily or propylthiouracil 400–600 mg daily). Usually, this results in subjective improvement within 10–14 days and renders the patient clinically and biochemically euthyroid at 6–8 weeks. At this point, the dose can be reduced and titrated to maintain T4 and TSH within their reference range. In most patients, carbimazole is continued at 5–20 mg per day for 12–18 months in the hope that remission will occur. Between 50% and 70% of patients with Graves’s disease will subsequently relapse, usually within 2 years of stopping treatment. Risk factors for relapse include younger age, male sex, presence of a goitre, and higher TRAb titres at both diagnosis and cessation of antithyroid therapy. Rarely, T4 and TSH levels fluctuate between those of thyrotoxicosis and hypothyroidism at successive review appointments, despite good drug adherence, presumably due to rapidly changing concentrations of TRAb. In these patients, satisfactory control can be achieved by blocking thyroid hormone synthesis with carbimazole 30–40 mg daily and adding levothyroxine 100–150 μg daily as replacement therapy (a “block and replace” regime).

Antithyroid drugs can have adverse effects. The most common is a rash. Agranulocytosis is a rare but potentially serious complication that cannot be predicted by routine measurement of white blood cell count but which is reversible on stopping treatment. Patients should be warned to stop the drug and seek medical advice immediately, should a severe sore throat or fever develop while on treatment. Propylthiouracil is associated with a small but definite risk of hepatotoxicity, which, in some instances, has resulted in liver failure requiring liver transplantation, and even in death. It should therefore be considered second-line therapy to carbimazole and be used only during pregnancy or breastfeeding (p. 1279), or if an adverse reaction to carbimazole has occurred.

| 18.14 Comparison of treatments for the thyrotoxicosis of Graves’ disease |
|-----------------|-----------------|-----------------|-----------------|
| **Management**  | **Common indications** | **Contraindications** | **Disadvantages/complications** |
| **Antithyroid drugs** (carbimazole, propylthiouracil) | First episode in patients <40 years | Breastfeeding (propylthiouracil suitable) | Hypersensitivity rash 2% |
| | | | Agranulocytosis 0.2% |
| | | | Hepatotoxicity (with propylthiouracil) |
| | | | Very rare but potentially fatal |
| | | | >50% relapse rate usually within 2 years of stopping drug |
| **Subtotal thyroidectomy** | Large goitre | Previous thyroid surgery | Hypothyroidism (~25%) |
| | Poor drug adherence, especially in young patients | Dependence on voice, e.g. opera singer, lecturer | Transient hypocalcaemia (10%) |
| | Recurrent thyrotoxicosis after course of antithyroid drugs in young patients | | Permanent hypoparathyroidism (1%) |
| | | | Recurrent laryngeal nerve palsy (1%) |
| **Radio-iodine** | Patients >40 years | Pregnancy or planned pregnancy within 6 months of treatment | Hypothyroidism: ~40% in first year, 80% after 15 years |
| | Recurrence following surgery irrespective of age | Active Graves’ ophthalmopathy | Most likely treatment to result in exacerbation of ophthalmopathy |
| | Other serious comorbidity | | |

*1A near-total thyroidecomy is now the favoured operation for Graves’s thyrotoxicosis in many institutions and is associated with a higher risk of some complications, including hypothyroidism (nearly 100%), but a reduced risk of persistent or recurrent thyrotoxicosis. It is not only vocal cord palsy due to recurrent laryngeal nerve damage that alters the voice following thyroid surgery; the superior laryngeal nerves are frequently transected and this results in minor changes in voice quality. In many institutions, 131I is used more liberally and is prescribed for much younger patients. * The extent to which radio-iodine exacerbates ophthalmopathy is controversial and practice varies; some use prednisolone to reduce this risk.
**Thyroid surgery** Patients should be rendered euthyroid with antithyroid drugs before operation. Oral potassium iodide, 60 mg three times daily, is often added for 10 days before surgery to inhibit thyroid hormone release and reduce the size and vascularity of the gland, making surgery technically easier. Traditionally, a ‘subtotal’ thyroidectomy is performed, in which a portion of one lobe of the thyroid is left in situ, with the aim of rendering the patient euthyroid. While complications of surgery are rare and 80% of patients are euthyroid, 15% are permanently hypothyroid and 5% remain thyrotoxic. As a consequence, many endocrine surgeons now opt to perform a ‘near-total’ thyroidectomy, leaving behind only a small portion of gland adjacent to the recurrent laryngeal nerves. This strategy invariably results in permanent hypothyroidism and is probably associated with a higher risk of hypoparathyroidism, but maximises the potential for cure of thyrotoxicosis.

**Radioactive iodine** $^{131}$I is administered orally as a single dose and is trapped and organified in the thyroid (see Fig. 18.3). $^{131}$I emits both $\beta$ and $\gamma$ radiation and, although it decays within a few weeks, it has long-lasting inhibitory effects on survival and replication of follicular cells. The variable radio-iodine uptake and radiosensitivity of the gland means that the choice of dose is empirical; in most centres, approximately 400–600 MBq (approximately 10–15 mCi) is administered. This regimen is effective in 75% of patients within 4–12 weeks. During the lag period, symptoms can be controlled by a $\beta$-blocker or, in more severe cases, by carbimazole. However, carbimazole reduces the efficacy of $^{131}$I therapy because it prevents organification of $^{131}$I in the gland, and so should be avoided until 48 hours after radio-iodine administration. If thyrotoxicosis persists after 6 months, a further dose of $^{131}$I can be given. The disadvantage of $^{131}$I treatment is that the majority of patients eventually develop hypothyroidism. $^{131}$I is usually avoided in patients with Graves’ ophthalmopathy and evidence of significant active orbital inflammation. It can be administered with caution in those with mild or ‘burnt-out’ eye disease, when it is customary to cover the treatment with a 6-week tapering course of oral prednisolone. In women of reproductive age, pregnancy must be excluded before administration of $^{131}$I and avoided for 6 months thereafter; men are also advised against fathering children for 6 months after receiving $^{131}$I.

**Thyrotoxicosis in pregnancy** Thyrotoxicosis in pregnancy may be associated with significant maternal and fetal morbidity. Management is very specialised and is discussed on page 1279 (see also Box 18.18).

**Thyrotoxicosis in adolescence** Thyrotoxicosis can occasionally occur in adolescence and is almost always due to Graves’ disease. The presentation may be atypical and management challenging, as summarised in Box 18.15.

**Graves’ ophthalmopathy** This condition is immunologically mediated but the autoantigen has not been identified. Within the orbit (and the dermis) there is cytokine-mediated proliferation of fibroblasts that secrete hydrophilic glycosaminoglycans. The resulting increase in interstitial fluid content, combined with a chronic inflammatory cell infiltrate, causes marked swelling and ultimately fibrosis of the extraocular muscles (Fig. 18.8) and a rise in retrobulbar pressure. The eye is displaced forwards (proptosis, exophthalmos, p. 631) and in severe cases there is optic nerve compression.

**Box 18.15. Thyrotoxicosis in adolescence**

- **Presentation:** may present with a deterioration in school performance or symptoms suggestive of attention deficit hyperactivity disorder.
- **Antithyroid drug therapy:** prolonged courses may be required because remission rates following an 18-month course of therapy are much lower than in adults.
- **Adherence:** adherence to antithyroid drug therapy is often suboptimal, resulting in poor disease control that may adversely affect performance at school.
- **Radio-iodine therapy:** usually avoided in adolescents because of concerns about risk of future malignancy.

**Fig. 18.8 Graves’ disease.** [A] Bilateral ophthalmopathy in a 42-year-old man. The main symptoms were diplopia in all directions of gaze and reduced visual acuity in the left eye. The periorbital swelling is due to retrobulbar fat prolapsing into the eyelids, and increased interstitial fluid as a result of raised intraorbital pressure. [B] Transverse CT of the orbits, showing the enlarged extraocular muscles. This is most obvious at the apex of the left orbit (arrow), where compression of the optic nerve caused reduced visual acuity.  

Ophthalmopathy, like thyrotoxicosis (see Fig. 18.7), typically follows an episodic course and it is helpful to distinguish patients with active inflammation (periorbital oedema and conjunctival inflammation with changing orbital signs) from those in whom the inflammation has ‘burnt out’. Eye disease is detectable in up to 50% of thyrotoxic patients at presentation, but active ocular inflammation may occur before or after thyrotoxic episodes (exophthalmic Graves’ disease). It is more common in cigarette smokers and is exacerbated by poor control of thyroid function, especially hypothyroidism. The most frequent presenting symptoms are related to increased exposure of the cornea, resulting from proptosis and lid retraction. There may be excessive lacrimation made worse by wind and bright light, a ‘gritty’ sensation in the eye, and pain due to conjunctivitis or corneal ulceration. In addition, there may be reduction of
visual acuity and/or visual fields as a consequence of corneal oedema or optic nerve compression. Other signs of optic nerve compression include reduced colour vision and a relative afferent pupillary defect (pp. 631 and 1088). If the extraocular muscles are involved and do not act in concert, diplopia results.

The majority of patients require no treatment other than reassurance. Smoking cessation should be actively encouraged. Methylcellulose eye drops and gel counter the gritty discomfort of dry eyes, and tinted glasses or side shields attached to spectacle frames reduce the excessive lacrimation triggered by sun or wind. In patients with mild Graves’ ophthalmopathy, oral selenium (100 μg twice daily for 6 months) improves quality of life, reduces ocular involvement and slows progression of disease; the mechanism of action is not known but may relate to an antioxidant effect. More severe inflammatory episodes are treated with glucocorticoids (e.g. pulsed intravenous methylprednisolone) and sometimes orbital radiotherapy. There is also an increasing trend to use alternative immunosuppressive therapies, such as rituximab and ciclosporin. Loss of visual acuity is an indication for urgent surgical decompression of the orbit. In ‘burnt-out’ disease, surgery to the extraocular muscles, and later the eyelids, may improve diplopia, conjunctival exposure and cosmetic appearance.

Pretibial myxoedema

This infiltrative dermopathy occurs in fewer than 5% of patients with Graves’ disease and has similar pathological features as occur in the orbit. It takes the form of raised pink-coloured or purplish plaques on the anterior aspect of the leg, extending on to the dorsum of the foot (p. 630). The lesions may be itchy and the skin may have a ‘peau d’orange’ appearance with growth of coarse hair; less commonly, the face and arms are affected. Treatment is rarely required but in severe cases topical glucocorticoids may be helpful.

Hashimoto’s thyroiditis

Hashimoto’s thyroiditis is characterised by destructive lymphoid infiltration of the thyroid, ultimately leading to a varying degree of fibrosis and thyroid enlargement. There is an increased risk of thyroid lymphoma (p. 650), although this is exceedingly rare. The nomenclature of autoimmune hypothyroidism is confusing. Some authorities reserve the term ‘Hashimoto’s thyroiditis’ for the condition of patients with positive antithyroid peroxidase autoantibodies and a firm goitre who may or may not be hypothyroid, and use the term ‘spontaneous atrophic hypothyroidism’ for the condition of hypothyroid patients without a goitre in whom TSH receptor-blocking antibodies may be more important than antithyroid peroxidase antibodies. However, these syndromes can both be considered as variants of the same underlying disease process.

Hashimoto’s thyroiditis increases in incidence with age and affects approximately 3.5 per 1000 women and 0.8 per 1000 men each year. Many present with a small or moderately sized diffuse goitre, which is characteristically firm or rubbery in consistency. Around 25% of patients are hypothyroid at presentation. In the remainder, serum \(T_4\) is normal and TSH normal or raised, but these patients are at risk of developing overt hypothyroidism in future years. Antithyroid peroxidase antibodies are present in the serum in more than 90% of patients with Hashimoto’s thyroiditis. In those under the age of 20 years, antinuclear factor (ANF) may also be positive.

Levothyroxine therapy is indicated as treatment for hypothyroidism (p. 640) and also to shrink an associated goitre.

In this context, the dose of levothyroxine should be sufficient to suppress serum TSH to low but detectable levels.

### Transient thyroiditis

#### Subacute (de Quervain’s) thyroiditis

In its classical painful form, subacute inflammation of the thyroid gland occurring after infection with Coxsackie, mumps or adenoviruses. There is pain in the region of the thyroid that may radiate to the angle of the jaw and the ears, and is made worse by swallowing, coughing and movement of the neck. The thyroid is usually palpably enlarged and tender.

Systemic upset is common. Affected patients are usually females aged 20–40 years. Painless transient thyroiditis can also occur after viral infection and in patients with underlying autoimmune disease. The condition can also be precipitated by drugs, including interferon-α and lithium.

Irrespective of the clinical presentation, inflammation in the thyroid gland occurs and is associated with release of colloid and stored thyroid hormones, but also with damage to follicular cells and impaired synthesis of new thyroid hormones. As a result, \(T_4\) and TSH levels are raised for 4–6 weeks until the pre-formed colloid is depleted. Thereafter, there is usually a period of hypothyroidism of variable severity before the follicular cells recover and normal thyroid function is restored within 4–6 months (Fig. 18.9). In the thyrotoxic phase, the iodine uptake is low because the damaged follicular cells are unable to trap iodine and because TSH secretion is suppressed. Low-titre thyroid autoantibodies appear transiently in the serum, and the erythrocyte sedimentation rate (ESR) is usually raised. High-titre autoantibodies suggest an underlying autoimmune pathology and greater risk of recurrence and ultimate progression to hypothyroidism.

The pain and systemic upset usually respond to simple measures such as non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally, however, it may be necessary to prescribe prednisolone 40 mg daily for 3–4 weeks. The thyrotoxicosis is mild and treatment with a β-blocker is usually adequate. Antithyroid drugs are of no benefit because thyroid hormone synthesis is impaired rather than enhanced. Careful monitoring of thyroid function and symptoms is required so that levothyroxine can be prescribed temporarily in the hypothyroid phase. Care must be taken to identify patients presenting with hypothyroidism who

**Fig. 18.9 Thyroid function tests in an episode of transient thyroiditis.**

This pattern might be observed in classical subacute (de Quervain’s) thyroiditis, painless thyroiditis or post-partum thyroiditis. The duration of each phase varies between patients.
are in the later stages of a transient thyroiditis, since they are unlikely to require life-long levothyroxine therapy (see Fig. 18.6).

**Post-partum thyroiditis**

The maternal immune response, which is modified during pregnancy to allow survival of the fetus, is enhanced after delivery and may unmask previously unrecognized subclinical autoimmune thyroid disease. Surveys have shown that transient biochemical disturbances of thyroid function occur in 5–10% of women within 6 months of delivery (see Box 18.18). Those affected are likely to have antithyroid peroxidase antibodies in the serum in early pregnancy. Symptoms of thyroid dysfunction are rare and there is no association between postnatal depression and abnormal thyroid function tests. However, symptomatic thyrotoxicosis presenting for the first time within 12 months of childbirth is likely to be due to post-partum thyroiditis and the diagnosis is confirmed by a negligible radio-isotope uptake. The clinical course and treatment are similar to those of painless subacute thyroiditis (see above). Post-partum thyroiditis tends to recur after subsequent pregnancies, and eventually patients progress over a period of years to permanent hypothyroidism.

**Iodine-associated thyroid disease**

**Iodine deficiency**

Iodine is an essential micronutrient and is a key component of T₄ and T₃. The World Health Organisation (WHO) recommends a daily intake of iodine of 150 μg/day for adult men and women; higher levels are recommended for pregnant women (p. 1279). Dietary sources of iodine include seafood, dairy products, eggs and grains. Dietary iodine deficiency is a major worldwide public health issue, with an estimated one-third of the world population living in areas of iodine insufficiency. Iodine deficiency is particularly common in Central Africa, South-East Asia and the Western Pacific. It is associated with the development of thyroid nodules and goitre (endemic goitre); the reduced substrate available for thyroid hormone production increases thyroid activity to maximise iodine uptake and recycling, and this acts as a potent stimulus for enlargement of the thyroid and nodule formation. Most affected patients are euthyroid with normal or raised TSH levels, although hypothyroidism can occur with severe iodine deficiency. Suspected iodine deficiency can be assessed by measuring iodine in urine (either a 24-hour collection or a spot sample). Endemic goitre can be treated by iodine supplementation, and a reduction in nodule and goitre size can be seen, particularly if it is commenced in childhood. Iodine deficiency is not associated with an increased risk of Graves’ disease or thyroid cancer, but the high prevalence of nodular autonomy does result in an increased risk of thyrotoxicosis and this risk may be further increased by iodine supplementation. Conversely, iodine supplementation may also increase the prevalence of subclinical hypothyroidism and autoimmune hypothyroidism. These complex effects of iodine supplementation are further discussed below.

In pregnancy, iodine deficiency is associated with impaired brain development, and severe deficiency can cause cretinism. Worldwide, iodine deficiency is the most common cause of preventable impaired cognitive development in children (p. 1279). The WHO and other international organisations have made reversal of iodine deficiency a priority and have helped organise national supplementation programmes. These have mainly involved the iodisation of table salt, but have also included schemes to administer oral or intramuscular iodised oil to at-risk populations and the addition of iodine to wells supplying water to local communities. These schemes have been extremely effective in reducing the prevalence of iodine deficiency, but lower consumption of table salt has actually led to an increase in iodine deficiency in some developed countries like Australia and New Zealand.

**Iodine-induced thyroid dysfunction**

Iodine has complex effects on thyroid function. Very high concentrations of iodine inhibit thyroid hormone synthesis and release (known as the Wolff–Chaikoff effect) and this forms the rationale for iodine treatment in thyroid crisis (p. 637) and prior to thyroid surgery for thyrotoxicosis (p. 645). This is an autoregulatory response to protect the body from the sudden release of large amounts of thyroid hormone in response to the ingestion of a substantial load of iodine. This effect only lasts for about 10 days, after which it is followed by an ‘escape phenomenon’: essentially, the return to normal organisation of iodine and thyroid peroxidase action (see Fig. 18.3). Therefore, if iodine is given to prepare an individual with Graves’ disease for surgery, the operation must happen within 10–14 days; otherwise, a significant relapse of the thyrotoxicosis could occur.

Iodine deficiency and underlying thyroid disease can both moderate the effects of iodine on thyroid function. In iodine-deficient parts of the world, transient thyrotoxicosis may be precipitated by prophylactic iodisation programmes. In iodine-sufficient areas, thyrotoxicosis can be precipitated by iodine-containing radiographic contrast medium or expectorants in individuals who have underlying thyroid disease predisposing to thyrotoxicosis, such as multinodular goitre or Graves’ disease in remission. Induction of thyrotoxicosis by iodine is called the Jod–Basedow effect. Chronic excess iodine administration can also result in hypothyroidism; this is, in effect, a failure to escape from the Wolff–Chaikoff effect and usually occurs in the context of prior insult to the thyroid by, for example, autoimmune disease, thyroiditis, lithium, antithyroid drugs or surgery.

**Amiodarone**

The anti-arrhythmic agent amiodarone has a structure that is analogous to that of T₄ (Fig. 18.10) and contains huge amounts of iodine; a 200 mg dose contains 75 mg iodine. Amiodarone also has a cytotoxic effect on thyroid follicular cells and inhibits conversion of T₂ to T₃ (increasing the ratio of T₄:T₃). Most patients receiving amiodarone have normal thyroid function but up to 20% develop hypothyroidism or thyrotoxicosis, and so thyroid function should be monitored regularly. TSH provides the best indicator of thyroid function.

The thyrotoxicosis can be classified as either:

- type I: iodine-induced excess thyroid hormone synthesis in patients with an underlying thyroid disorder, such as

![Fig. 18.10 The structure of amiodarone. Note the similarities to T₄ (see Fig. 18.3).](image-url)
noddular goitre or latent Graves’ disease (an example of the Jod–Basedow effect).

- **type II**: thyroiditis due to a direct cytotoxic effect of amiodarone administration.

These patterns can overlap and may be difficult to distinguish clinically, as iodine uptake is low in both. There is no widely accepted management algorithm, although the iodine excess renders the gland resistant to $^{131}$I. Antithyroid drugs may be effective in patients with the type I form but are ineffective in type II thyrotoxicosis. Prednisolone is beneficial in the type II form. A pragmatic approach is to commence combination therapy with an antithyroid drug and glucocorticoid in patients with significant thyrotoxicosis. A rapid response (within 1–2 weeks) usually indicates a type II picture and permits withdrawal of the antithyroid therapy; a slower response suggests a type I picture, in which case antithyroid drugs may be continued and prednisolone withdrawn. Potassium perchlorate can also be used to inhibit iodine trapping in the thyroid. If the cardiac state allows, amiodarone should be discontinued, but it has a long half-life (50–60 days) and so its effects are long-lasting. To minimise the risk of type I thyrotoxicosis, thyroid function should be measured in all patients prior to commencement of amiodarone therapy, and amiodarone should be avoided if TSH is suppressed.

Hypothyroidism should be treated with levothyroxine, which can be given while amiodarone is continued.

### Simple and multinodular goitre

These terms describe diffuse or multinodular enlargement of the thyroid, which occurs sporadically and is of unknown aetiology.

#### Simple diffuse goitre

This form of goitre usually presents between the ages of 15 and 25 years, often during pregnancy, and tends to be noticed by friends and relatives rather than the patient. Occasionally, there is a tight sensation in the neck, particularly when swallowing. The goitre is soft and symmetrical, and the thyroid enlarged to two or three times normal. There is no tenderness, lymphadenopathy or overlying bruit. Concentrations of T3, T4 and TSH are normal and no thyroid autoantibodies are detected in the serum. No treatment is necessary and the goitre usually regresses. In some, however, the unknown stimulus to thyroid enlargement persists and, as a result of recurrent episodes of hyperplasia and involution during the following 10–20 years, the gland becomes multinodular with areas of autonomous function.

#### Multinodular goitre

The natural history is shown in Figure 18.11. Patients with thyroid enlargement in the absence of thyroid dysfunction or positive autoantibodies (i.e. with ‘simple goitre’; see above) as young adults may progress to develop nodules. These nodules grow at varying rates and secrete thyroid hormone ‘autonomously’, thereby suppressing TSH-dependent growth and function in the rest of the gland. Ultimately, complete suppression of TSH occurs in about 25% of cases, with T3 and T3 levels often within the reference range (subclinical thyrotoxicosis, p. 642), but sometimes elevated (toxic multinodular goitre; see Fig. 18.5).

### Clinical features and investigations

Multinodular goitre is usually diagnosed in patients presenting with thyrotoxicosis, a large goitre with or without tracheal compression, or sudden painful swelling caused by haemorrhage into a nodule or cyst. The goitre is nodular or lobulated on palpation and may extend retrosternally; however, not all multinodular goitres causing thyrotoxicosis are easily palpable. Very large goitres can cause mediastinal compression with stridor (Fig. 18.12), dysphagia and obstruction of the superior vena cava. Hoarseness due to recurrent laryngeal nerve palsy can occur but is far more suggestive of thyroid carcinoma.

The diagnosis can be confirmed by ultrasonography and/or thyroid scintigraphy (see Fig. 18.5). In patients with large goitres, a flow-volume loop is a good screening test for significant tracheal compression (see Fig. 17.7, p. 554). If intervention is contemplated, a CT or MRI of the thoracic inlet should be performed to quantify the degree of tracheal displacement or compression and the extent of retrosternal extension. Nodules should be evaluated for the possibility of thyroid neoplasia, as described on page 649.

### Management

If the goitre is small, no treatment is necessary but annual thyroid function testing should be arranged, as the natural history is progression to a toxic multinodular goitre. Thyroid surgery is indicated for large goitres that cause mediastinal compression.
or that are cosmetically unattractive. $^{131}$I can result in a significant reduction in thyroid size and may be of value in elderly patients. Levothyroxine therapy is of no benefit in shrinking multinodular goitres in iodine-sufficient countries and may simply aggravate any associated thyrotoxicosis.

In toxic multinodular goitre, treatment is usually with $^{131}$I. The iodine uptake is lower than in Graves’ disease, so a higher dose may be administered (up to 800 Mbic (approximately 20 mCi)) and hypothyroidism is less common. In thyrotoxic patients with a large goitre, thyroid surgery may be indicated. Long-term treatment with antithyroid drugs is not usually employed, as relapse is invariably after drug withdrawal; drug therapy is normally reserved for frail older patients in whom surgery or $^{131}$I is not an appropriate option.

Asymptomatic patients with subclinical thyrotoxicosis (p. 642) are increasingly being treated with $^{131}$I on the grounds that a suppressed TSH is a risk factor for atrial fibrillation and, particularly in post-menopausal women, osteoporosis.

### Thyroid neoplasia

Patients with thyroid tumours usually present with a solitary nodule (p. 642). Most are benign and a few of these, called ‘toxic adenomas’, secrete excess thyroid hormones. Primary thyroid malignancy is rare, accounting for less than 1% of all carcinomas, and has an incidence of 25 per million per annum. As shown in Box 18.16, it can be classified according to the cell type of origin. With the exception of medullary carcinoma, thyroid cancer is more common in females.

### Toxic adenoma

A solitary toxic nodule is the cause of less than 5% of all cases of thyrotoxicosis. The nodule is a follicular adenoma, which autonomously secretes excess thyroid hormones and inhibits endogenous TSH secretion, with subsequent atrophy of the rest of the thyroid gland. The adenoma is usually greater than 3 cm in diameter. Most patients are female and over 40 years of age. Although many nodules are palpable, the diagnosis can be made with certainty only by thyroid scintigraphy (see Fig. 18.5). The thyrotoxicosis is usually mild and in almost 50% of patients the plasma T₄, alone is elevated ($T₄$ thyrotoxicosis, $^{131}$I (400–800 Mbic (10–20 mCi)) is highly effective and is an ideal treatment since the atrophic cells surrounding the nodule do not take up iodine and so receive little or no radiation. For this reason, permanent hypothyroidism is unusual. Hemithyroidectomy is an alternative management option.

### Differentiated carcinoma

**Papillary carcinoma**

This is the most common of the malignant thyroid tumours and accounts for 90% of radiation-induced thyroid cancer. It may be multifocal and spread is initially to regional lymph nodes. Some patients present with cervical lymphadenopathy and no apparent thyroid enlargement; in such instances, the primary lesion may be less than 10 mm in diameter.

**Follicular carcinoma**

This is usually a single encapsulated lesion. Spread to cervical lymph nodes is rare. Metastases are blood-borne and are most often found in bone, lungs and brain.

### Management

The management of thyroid cancers should be individualised and planned in multidisciplinary team meetings that include all specialists involved in the service; this should include thyroid surgeons, endocrinologists, oncologists, pathologists, radiologists and nurse specialists. Large tumours, those with adverse histological features and/or tumours with metastatic disease at presentation are usually managed by total thyroidectomy followed by a large dose of $^{131}$I (1100 or 3700 Mbic (approximately 30 or 100 mCi)) to ablate any remaining normal or malignant thyroid tissue. Thereafter, long-term treatment with levothyroxine in a dose sufficient to suppress TSH (usually 150–200 μg daily) is given, as there is evidence that growth of differentiated thyroid carcinomas is TSH-dependent. Smaller tumours with no adverse histological features may require only thyroid lobectomy.

Follow-up involves measurement of serum thyroglobulin, which should be undetectable in patients whose normal thyroid has been ablated and who are taking a suppressive dose of levothyroxine. Thyroglobulin antibodies may interfere with the assay and, depending on the method employed, may result in a falsely low or high result. Detectable thyroglobulin, in the absence of assay interference, is suggestive of tumour recurrence or metastases, particularly if the thyroglobulin titre is rising across serial measurements. Local recurrence or metastatic disease may be localised by ultrasound, CT, MRI and/or whole-body scanning with $^{131}$I, and may be treated with further surgery and/or $^{131}$I therapy. $^{131}$I treatment in thyroid cancer and isotope scanning both require serum TSH concentrations to be elevated (>20 mIU/L). This may be achieved by stopping levothyroxine for 4–6 weeks, inducing symptomatic hypothyroidism, or by administering intramuscular injections of recombinant human TSH. Patients usually find the latter approach preferable but it is more expensive. Those with locally advanced or metastatic papillary and follicular carcinoma that is refractive to $^{131}$I may be considered for therapy with sorafenib or lenvatinib. These drugs are multi-targeted tyrosine kinase inhibitors and have been shown in trials to prolong progression-free survival by between 5 and 14 months. They have multiple toxicities, however, including poor appetite, weight loss, fatigue, diarrhoea, mucositis, rashes, hypertension and blood dyscrasias. The potential benefits of

*Patients with medullary carcinoma as part of multiple endocrine neoplasia (MEN) types 2 and 3 (p. 688) may present in childhood.*
therapy therefore have to be carefully weighed against side-effects that can significantly impair quality of life.

**Prognosis**

Most patients with papillary and follicular thyroid cancer will be cured with appropriate treatment. Adverse prognostic factors include older age at presentation, the presence of distant metastases, male sex and certain histological subtypes. However, $^{131}$I therapy can be effective in treating those with distant metastases, particularly small-volume disease in the lungs, and so prolonged survival is quite common.

### Anaplastic carcinoma and lymphoma

These two conditions are difficult to distinguish clinically but are distinct cytologically and histologically. Patients are usually over 60 years of age and present with rapid thyroid enlargement over 2–3 months. The goitre is hard and there may be stridor due to tracheal compression and hoarseness due to recurrent laryngeal nerve palsy. There is no effective treatment for anaplastic carcinoma, although surgery and radiotherapy may be considered in some circumstances. In older patients, median survival is only 7 months.

The prognosis for lymphoma, which may arise from pre-existing Hashimoto’s thyroiditis, is better (p. 961), with a median survival of 9 years. Some 98% of tumours are non-Hodgkin’s lymphomas, usually the diffuse large B-cell subtype. Treatment is with combination chemotherapy and external beam radiotherapy (p. 965).

### Medullary carcinoma

This tumour arises from the parafollicular C cells of the thyroid. In addition to calcitonin, the tumour may secrete 5-hydroxytryptamine (5-HT, serotonin), various peptides of the tachykinin family, adrenocorticotrophic hormone (ACTH) and prostaglandins. As a consequence, carcinoid syndrome (p. 678) and Cushing’s syndrome (p. 666) may occur.

Patients usually present in middle age with a firm thyroid mass. Cervical lymph node involvement is common but distant metastases are rare initially. Serum calcitonin levels are raised and are useful in monitoring response to treatment. Despite the very high levels of calcitonin found in some patients, hypocalcaemia is extremely rare; however, hypercalcitoninaemia can be associated with severe, watery diarrhoea.

Treatment is by total thyroidectomy with removal of regional cervical lymph nodes. Since the C cells do not concentrate iodine and are not responsive to TSH, there is no role for $^{131}$I therapy or TSH suppression with levothyroxine. External beam radiotherapy may be considered in some patients at high risk of local recurrence. Vandetanib and cabozantinib are tyrosine kinase inhibitors licensed for patients with progressive advanced medullary cancer. The prognosis is less good than for papillary and follicular carcinoma, but individuals can live for many decades with persistent disease that behaves in an indolent fashion.

Medullary carcinoma of the thyroid occurs sporadically in 70–90% cases; in 10–30% of cases, there is a genetic predisposition that is inherited in an autosomal dominant fashion and is due to an activating mutation in the RET gene. This inherited tendency normally forms part of one of the MEN syndromes (MEN 2 (also known as MEN 2a) or MEN 3 (also known as MEN 2b), p. 688) but, occasionally, susceptibility to medullary carcinoma is the only inherited trait (familial medullary thyroid cancer).

### Riedel’s thyroiditis

This is not a form of thyroid cancer but the presentation is similar and the differentiation can usually be made only by thyroid biopsy. It is an exceptionally rare condition of unknown aetiology, in which there is extensive infiltration of the thyroid and surrounding structures with fibrous tissue. There may be associated mediastinal and retroperitoneal fibrosis. Presentation is with a slow-growing goitre that is irregular and stony-hard. There is usually tracheal and oesophageal compression necessitating partial thyroidectomy. Other recognised complications include recurrent laryngeal nerve palsy, hypoparathyroidism and eventually hypothyroidism.

### Congenital thyroid disease

Early treatment with levothyroxine is essential to prevent irreversible brain damage in children (cretinism) with congenital hypothyroidism. Routine screening of TSH levels in heel-prick blood samples obtained 5–7 days after birth (as part of the Guthrie test) has revealed an incidence of approximately 1 in 3000, resulting from thyroid agenesis, ectopic or hypoplastic glands, or dyshormonogenesis. Congenital hypothyroidism is thus six times more common than phenylketonuria. It is now possible to start levothyroxine replacement therapy within 2 weeks of birth. Developmental assessment of infants treated at this early stage has revealed no differences between cases and controls in most children.

### Dyshormonogenesis

Several autosomal recessive defects in thyroid hormone synthesis have been described; the most common results from deficiency of the intrathyroidal peroxidase enzyme. Homozygous individuals present with congenital hypothyroidism; heterozygotes present in the first two decades of life with goitre, normal thyroid hormone levels and a raised TSH. The combination of dyshormonogenetic goitre and nerve deafness is known as Pendred’s syndrome and is due to mutations in pendrin, the protein that transports iodide to the luminal surface of the follicular cell (see Fig. 18.3).
Functional anatomy, physiology and investigations

The physiology of male and female reproductive function is illustrated in Figures 18.13 and 18.14, respectively. Pathways for synthesis of sex steroids are shown in Figure 18.19 (p. 667).

The male

In the male, the testis serves two principal functions: synthesis of testosterone by the interstitial Leydig cells under the control of luteinising hormone (LH), and spermatogenesis by Sertoli cells under the control of follicle-stimulating hormone (FSH) (but also requiring adequate testosterone). Negative feedback suppression of LH is mediated principally by testosterone, while secretion of another hormone by the testis, inhibin, suppresses FSH.

The axis can be assessed easily by a random blood sample for testosterone, LH and FSH. Testosterone levels are higher in the morning and therefore, if testosterone is marginally low, sampling should be repeated with the patient fasted at 0900 hrs. Testosterone is largely bound in plasma to sex hormone-binding globulin and this can also be measured to calculate the ‘free androgen index’ or the ‘bioavailable’ testosterone. Testicular function can also be tested by semen analysis.

There is no equivalent of the menopause in men, although testosterone concentrations decline slowly from the fourth decade onwards.
The female

In the female, physiology varies during the normal menstrual cycle. FSH stimulates growth and development of ovarian follicles during the first 14 days after the menses. This leads to a gradual increase in oestradiol production from granulosa cells, which initially suppresses FSH secretion (negative feedback) but then, above a certain level, stimulates an increase in both the frequency and amplitude of gonadotrophin-releasing hormone (GnRH) pulses, resulting in a marked increase in LH secretion (positive feedback). The mid-cycle 'surge' of LH induces ovulation. After release of the ovum, the follicle differentiates into a corpus luteum, which secretes progesterone. Unless pregnancy occurs during the cycle, the corpus luteum regresses and the fall in progesterone levels results in menstrual bleeding. Circulating levels of oestrogen and progesterone in pre-menopausal women are, therefore, critically dependent on the time of the cycle. The most useful 'test' of ovarian function is a careful menstrual history: if menses are regular, measurement of gonadotrophins and oestrogen is not necessary. In addition, ovulation can be confirmed by measuring plasma progesterone levels during the luteal phase ('day 21 progesterone').

Cessation of menstruation (the menopause) occurs at an average age of approximately 50 years in developed countries. In the 5 years before, there is a gradual increase in the number of anovulatory cycles and this is referred to as the climacteric. Oestrogen and inhibit secretion falls and negative feedback results in increased pituitary secretion of LH and FSH (both typically to levels above 30 IU/L (3.3 μg/L)).

The pathophysiology of male and female reproductive dysfunction is summarised in Box 18.19.
The differential diagnosis is shown in Box 18.20. Puberty is considered to be delayed if the onset of the physical features of sexual maturation has not occurred by a chronological age that is 2.5 standard deviations (SD) above the national average. In the UK, this is by the age of 14 in boys and 13 in girls. Genetic factors have a major influence in determining the timing of the onset of puberty, such that the age of menarche (the onset of menstruation) is often comparable within sibling and mother–daughter pairs and within ethnic groups. However, because there is also a threshold for body weight that acts as a trigger for normal puberty, the onset of puberty can be influenced by other factors including nutritional status and chronic illness (p. 694).

Clinical assessment

The differential diagnosis is shown in Box 18.20. The key issue is to determine whether the delay in puberty is simply because the ‘clock is running slow’ (constitutional delay of puberty) or because there is pathology in the hypothalamus/pituitary (hypogonadotrophic hypogonadism) or the gonads (hypergonadotrophic hypogonadism). A general history and physical examination should be performed with particular reference to previous or current medical disorders, social circumstances and family history. Body proportions, sense of smell and pubertal stage should be carefully documented and, in boys, the presence or absence of testes in the scrotum noted. Current weight and height may be plotted on centile charts, along with parental heights. Previous growth measurements in childhood, which can usually be obtained from health records, are extremely useful. Healthy growth usually follows a centile. Usually, children with constitutional delay have always been small but have maintained a normal growth velocity that is appropriate for bone age. Poor linear growth, with ‘crossing of the centiles’, is more likely to be associated with acquired disease. Issues that are commonly encountered in the management of adolescents with delayed puberty are summarised in Box 18.21.

Constitutional delay of puberty

This is the most common cause of delayed puberty, but is a much more frequent explanation for lack of pubertal development in boys than in girls. Affected children are healthy and have usually been more than 2 SD below the mean height for their age throughout childhood. There is often a history of delayed puberty in siblings or parents. Since sex steroids are essential for fusion of the epiphyses, ‘bone age’ can be estimated by X-rays of epiphyses, usually in the wrist and hand; in constitutional delay, bone age is lower than chronological age. Constitutional delay of puberty should be considered as a normal variant, as puberty will commence spontaneously. However, affected children can experience significant psychological distress because of their lack of physical development, particularly when compared with their peers.

Hypergonadotrophic hypogonadism

This may be due to structural, inflammatory or infiltrative disorders of the pituitary and/or hypothalamus (see Box 18.54, p. 681). In such circumstances, other pituitary hormones, such as growth hormone, are also likely to be deficient.

‘Functional’ gonadotrophin deficiency is caused by a variety of factors, including low body weight, chronic systemic illness (as a consequence of the disease itself or secondary malnutrition), endocrine disorders and profound psychosocial stress.

Isolated gonadotrophin deficiency is usually due to a genetic abnormality that affects the synthesis of either GnRH or gonadotrophins. The most common form is Kallmann’s syndrome, in which there is primary GnRH deficiency and, in most affected individuals, agenesis or hypoplasia of the olfactory bulbs, resulting in anosmia or hyposmia. If isolated gonadotrophin deficiency is left untreated, the epiphyses fail to fuse, resulting in tall stature with disproportionately long arms and legs relative to trunk height (eunuchoid habitus).

Cryptorchidism (undescended testes) and gynaecomastia are commonly observed in all forms of hypergonadotrophic hypogonadism.

18.21 Delayed puberty

| Aetiology: | in boys the most common cause is constitutional delay, whereas in girls there is inevitably a structural hypothalamic/pituitary abnormality or a factor that affects their function. |
| Psychological effects: | whatever the underlying cause, delayed puberty is often associated with substantial psychological distress. |
| Investigations: | a karyotype should be performed in all adolescents with hypergonadotrophic hypogonadism, to exclude Turner’s and Klinefelter’s syndromes, unless there is an obvious precipitating cause. |
| Medical induction of puberty: | if this is being considered, it needs to be managed carefully and carried out in a controlled fashion, to avoid premature fusion of the epiphyses. |
Precocious puberty

Precocious puberty (PP) is the early development of any secondary sexual characteristics before the age of 9 years in a boy and 6–8 years of age in a girl. Central PP is due to the early maturation of the hypothalamic–pituitary–gonadal axis and thus is gonadotrophin-dependent. It is more common in girls than boys and often no structural cause is identified, i.e. ‘the physiological clock is running fast’. Structural causes are found more commonly in younger children and in boys and include:

- central nervous system (CNS) tumours such as astrocytomas, germ-cell tumours secreting human chorionic gonadotrophin (hCG) and hypothalamic hamartomas
- CNS injury caused by infection, inflammation or trauma/surgery
- congenital CNS structural abnormalities.

Pseudo (or peripheral) PP is much less common, and is due to excess sex steroids in the absence of pituitary gonadotrophins, with causes including congenital adrenal hyperplasia and McCune–Albright syndrome (p. 1055).

Management

Social and psychological difficulties may accompany the onset of PP and the premature closure of the epiphyses can result in reduced final height. In central PP, development can be arrested with long-acting GnRH analogues. In both central and peripheral PP, treatment of any underlying cause is indicated.

Amenorrhoea

Primary amenorrhoea may be diagnosed in a female who has never menstruated; this usually occurs as a manifestation of delayed puberty but may also be a consequence of anatomical defects of the female reproductive system, such as endometrial hypoplasia or vaginal agenesis. Secondary amenorrhoea describes the cessation of menstruation in a female who has previously had periods. The causes of this common presentation are shown in Box 18.22. In non-pregnant women, secondary amenorrhoea is almost invariably a consequence of either ovarian or hypothalamic/pituitary dysfunction. Premature ovarian failure (premature menopause) is defined, arbitrarily, as occurring before 40 years of age. Rarely, endometrial adhesions (Asherman’s syndrome) can form after uterine curettage, surgery or infection with tuberculosis or schistosomiasis, preventing endometrial proliferation and shedding.

Clinical assessment

The underlying cause can often be suspected from associated clinical features and the patient’s age. Hypothalamic/pituitary disease and premature ovarian failure result in oestrogen deficiency, which causes a variety of symptoms usually associated with the menopause (Box 18.23). A history of galactorrhoea should be sought. Significant weight loss of any cause can cause amenorrhoea by suppression of gonadotrophins. Weight gain may suggest hypothyroidism, Cushing’s syndrome or, very rarely, a hypothalamic lesion. Hirsutism, obesity and long-standing irregular periods suggest polycystic ovarian syndrome.

Investigations

Measurement of basal and GnRH-stimulated gonadotrophin levels will allow categorisation into central or peripheral PP, with gonadotrophin levels rising in central PP. Imaging of the CNS is required in cases of central PP, while adrenal and ovarian imaging is indicated in peripheral PP.
syndrome (PCOS, p. 658). The presence of other autoimmune disease raises the possibility of autoimmune premature ovarian failure.

**Investigations**

Pregnancy should be excluded in women of reproductive age by measuring urine or serum hCG. Serum LH, FSH, oestriadiol, prolactin, testosterone, T₄ and TSH should be measured and, in the absence of a menstrual cycle, can be taken at any time. Investigation of hyperprolactinaemia is described on page 684. High concentrations of LH and FSH with low or low-normal oestriadiol suggest primary ovarian failure. Ovarian autoantibodies may be positive when there is an underlying autoimmune aetiology, and a karyotype should be performed in younger women to exclude mosaic Turner’s syndrome. Elevated LH, prolactin and testosterone levels with normal oestriadiol are common in PCOS. Low levels of LH, FSH and oestriadiol suggest hypothalamic or pituitary disease and a pituitary MRI is indicated.

There is some overlap in gonadotrophin and oestrogen concentrations between women with hypogonadotrophic hypogonadism and PCOS. If there is doubt as to the underlying cause of secondary amenorrhoea, then the response to 5 days of treatment with an oral progestogen (e.g. medroxyprogesterone acetate 10 mg twice daily) can be assessed. In women with PCOS, the progestogen will cause maturation of the endometrium and menstruation will occur a few days after the progestogen is stopped. In women with hypogonadotrophic hypogonadism, menstruation does not occur following progestogen withdrawal because the endometrium is atrophic as a result of oestrogen deficiency. If doubt persists in distinguishing oestrogen deficiency from a uterine abnormality, the capacity for menstruation can be tested with 1 month of treatment with cyclic oestrogen and progestogen (usually administered as a combined oral contraceptive pill).

Assessment of bone mineral density by dual X-ray absorptiometry (DXA, p. 989) may be appropriate in patients with low androgen and oestrogen levels.

**Management**

Where possible, the underlying cause should be treated. For example, women with functional amenorrhoea due to excessive exercise and low weight should be encouraged to reduce their exercise and regain some weight. The management of structural pituitary and hypothalamic disease is described on page 684 and that of PCOS on page 658.

In oestrogen-deficient women, replacement therapy may be necessary to treat symptoms and/or to prevent osteoporosis. Women who have had a hysterectomy can be treated with oestrogen alone but those with a uterus should be treated with combined oestrogen/progestogen therapy, since unopposed oestrogen increases the risk of endometrial cancer. Cyclical hormone replacement therapy (HRT) regimens typically involve giving oestrogen on days 1–21 and progestogen on days 14–21 of the cycle, and this can be conveniently administered as the oral contraceptive pill. If oestrogenic side-effects (fluid retention, weight gain, hypertension and thrombosis) are a concern, then lower-dose oral or transdermal HRT may be more appropriate.

The timing of the discontinuation of oestrogen replacement therapy is still a matter of debate. In post-menopausal women, HRT has been shown to relieve menopausal symptoms and to prevent osteoporotic fractures but is associated with adverse effects, which are related to the duration of therapy and to the patient’s age. In patients with premature menopause, HRT should be continued up to the age of around 50 years, but continued beyond this age only if there are continued symptoms of oestrogen deficiency on discontinuation.

Management of infertility in oestrogen-deficient women is described on page 656.

**Male hypogonadism**

The clinical features of both hypo- and hypergonadotrophic hypogonadism include loss of libido, lethargy with muscle weakness, and decreased frequency of shaving. Patients may also present with gynaecomastia, infertility, delayed puberty, osteoporosis or anaemia of chronic disease. The causes of hypogonadism are listed in Box 18.20. Mild hypogonadism may also occur in older men, particularly in the context of central adiposity and the metabolic syndrome (p. 730). Postulated mechanisms are complex and include reduction in sex hormone-binding globulin by insulin resistance and reduction in GnRH and gonadotrophin secretion by cytokines or oestrogen released by adipose tissue. Testosterone levels also fall gradually with age in men (see Box 18.30) and this is associated with gonadotrophin levels that are low or inappropriately within the ‘normal’ range. There is an increasing trend to measure testosterone in older men, typically as part of an assessment of erectile dysfunction and lack of libido.

**Investigations**

Male hypogonadism is confirmed by demonstrating a low fasting 0900-hr serum testosterone level. The distinction between hypo- and hypergonadotrophic hypogonadism is by measurement of random LH and FSH. Patients with hypogonadotrophic hypogonadism should be investigated as described for pituitary disease on page 680. Patients with hypergonadotrophic hypogonadism should have the testes examined for cryptorchidism or atrophy, and a karyotype should be performed (to identify Klinefelter’s syndrome).

**Management**

Testosterone replacement is clearly indicated in younger men with significant hypogonadism to prevent osteoporosis and to restore muscle power and libido. Debate exists as to whether replacement therapy is of benefit in mild hypogonadism associated with ageing and central adiposity, particularly in the absence of structural pituitary/hypothalamic disease or other pituitary hormone deficiency. In such instances, a therapeutic trial of testosterone therapy may be considered if symptoms are present (e.g. low libido and erectile dysfunction), but the benefits of therapy must be carefully weighed against the potential for harm.

Routes of testosterone administration are shown in Box 18.24. First-pass hepatic metabolism of testosterone is highly efficient, so bioavailability of ingested preparations is poor. Doses of systemic testosterone can be titrated against symptoms; circulating testosterone levels may provide only a rough guide to dosage because they may be highly variable (Box 18.24). Testosterone therapy can aggravate prostatic carcinoma; prostate-specific antigen (PSA) should be measured before commencing testosterone therapy in men older than 50 years and monitored annually thereafter. Haemoglobin concentration should also be monitored in older men, as androgen replacement can cause polycythaemia. Testosterone replacement inhibits spermatogenesis; treatment for fertility is described below.
Infertility

Infertility affects around 1 in 7 couples of reproductive age, often causing psychological distress. The main causes are listed in Box 18.25. In women, it may result from anovulation or abnormalities of the reproductive tract that prevent fertilisation or embryonic implantation, often damaged Fallopian tubes from previous infection. In men, infertility may result from impaired sperm quality (e.g. reduced motility) or reduced sperm number. Azoospermia or oligospermia is usually idiopathic but may be a consequence of hypogonadism (see Box 18.20). Microdeletions of the Y chromosome are increasingly recognised as a cause of severely abnormal spermatogenesis. In many couples, more than one factor causing subfertility is present, and in a large proportion no cause can be identified.

Clinical assessment

A history of previous pregnancies, relevant infections and surgery is important in both men and women. A sexual history must be explored sensitively, as some couples have intercourse infrequently or only when they consider the woman to be ovulating, and psychosexual difficulties are common. Irregular and/or infrequent menstrual periods are an indicator of anovulatory cycles in the woman, in which case causes such as PCOS should be considered. In men, the testes should be examined to confirm that both are in the scrotum and to identify any structural abnormality, such as small size, absent vas deferens or the presence of a varicocele.

Investigations

Investigations should generally be performed after a couple has failed to conceive despite unprotected intercourse for 12 months, unless there is an obvious abnormality like amenorrhoea. Both partners need to be investigated. The male partner needs a semen analysis to assess sperm count and quality. Home testing for ovulation (by commercial urine dipstick kits, temperature measurement, or assessment of cervical mucus) is not recommended, as the information is often counterbalanced by increased anxiety if interpretation is inconclusive. In women with regular periods, ovulation can be confirmed by an elevated serum progesterone concentration on day 21 of the menstrual cycle. Transvaginal ultrasound can be used to assess uterine and ovarian anatomy. Tubal patency may be examined by laparoscopy or by hysterosalpingography (HSG; a radio-opaque medium is injected into the uterus and should normally outline the Fallopian tubes). In vitro assessments of sperm survival in cervical mucus may be done in cases of unexplained infertility but are rarely helpful.

Management

Couples should be advised to have regular sexual intercourse, ideally every 2–3 days throughout the menstrual cycle. It is not uncommon for ‘spontaneous’ pregnancies to occur in couples undergoing investigations for infertility or with identified causes of male or female subfertility.

In women with anovulatory cycles secondary to PCOS (p. 658), clomifene, which has partial anti-oestrogen action, blocks negative feedback of oestrogen on the hypothalamus/pituitary, causing gonadotrophin secretion and thus ovulation. In women with gonadotrophin deficiency or in whom anti-oestrogen therapy is unsuccessful, ovulation may be induced by direct stimulation of the ovary by daily injection of FSH and an injection of hCG to

**18.25 Causes of infertility**

**Female factor (35–40%)**
- Ovulatory dysfunction:
  - Polycystic ovarian syndrome
  - Hypogonadotropic hypogonadism (see Box 18.20)
  - Hypergonadotropic hypogonadism (see Box 18.20)
- Tubular dysfunction:
  - Pelvic inflammatory disease (chlamydia, gonorrhoea)
  - Endometriosis
  - Previous sterilisation
  - Previous pelvic or abdominal surgery
- Cervical and/or uterine dysfunction:
  - Congenital abnormalities
  - Fibroids
  - Treatment for cervical carcinoma
  - Asherman’s syndrome

**Male factor (35–40%)**
- Reduced sperm quality or production:
  - Y chromosome microdeletions
  - Varicocele
  - Hypergonadotropic hypogonadism (see Box 18.20)
  - Hypogonadotropic hypogonadism (see Box 18.20)
- Tubular dysfunction:
  - Varicocele
  - Congenital abnormality of vas deferens/epididymis
  - Previous sexually transmitted infection (chlamydia, gonorrhoea)
  - Previous vasectomy
- Unexplained or mixed factor (20–35%)
induce follicular rupture at the appropriate time. In hypothalamic
disease, pulsatile GnRH therapy with a portable infusion pump
can be used to stimulate pituitary gonadotrophin secretion
(note that non-pulsatile administration of GnRH or its analogues
paradoxically suppresses LH and FSH secretion). Whatever
method of ovulation induction is employed, monitoring of response
is essential to avoid multiple ovulation. For clomifene, ultrasound
monitoring is recommended for at least the first cycle. During
gonadotrophin therapy, closer monitoring of follicular growth
by transvaginal ultrasonography and blood oestradiol levels is
mandatory. ‘Ovarian hyperstimulation syndrome’ is characterised
by grossly enlarged ovaries and capillary leak with circulatory
shock, pleural effusions and ascites. Anovulatory women who fail
to respond to ovulation induction or who have primary ovarian
failure may wish to consider using donated eggs or embryos,
surrogacy and adoption.

Surgery to restore Fallopian tube patency can be effective but
in vitro fertilisation (IVF) is normally recommended. IVF is widely
used for many causes of infertility and in unexplained cases of
prolonged (>3 years) infertility. The success of IVF depends on
age, with lower success rates in women over 40 years.

Men with hypogonadotrophic hypogonadism who wish
fertility are usually given injections of hCG several times a
week (recombinant FSH may also be required in men with
hypogonadism of pre-pubertal origin); it may take up to 2 years
to achieve satisfactory sperm counts. Surgery is rarely an option
in primary testicular disease but removal of a varicocele can
improve semen quality. Extraction of sperm from the epididymis
for IVF, and intracytoplasmic sperm injection (ICSI, when single
spermatozoa are injected into each oocyte) are being used
increasingly in men with oligospermia or poor sperm quality who
have primary testicular disease. Azoospermic men may opt to
use donated sperm but this may be in short supply.

Gynaecomastia

Gynaecomastia is the presence of glandular breast tissue in males.
Normal breast development in women is oestrogen-dependent,
while androgens oppose this effect. Gynaecomastia results from
an imbalance between androgen and oestrogen activity, which
may reflect androgen deficiency or oestrogen excess. Causes
are listed in Box 18.26. The most common are physiological: for
example, in the newborn baby (due to maternal and placental
oestrogens), in pubertal boys (in whom oestradiol concentrations
reach adult levels before testosterone) and in elderly men (due
to decreasing testosterone concentrations). Prolactin excess
alone does not cause gynaecomastia (p. 684).

Clinical assessment

A drug history is important. Gynaecomastia is often asymmetrical
and palpation may allow breast tissue to be distinguished from
the prominent adipose tissue (lipomastia) around the nipple that
is often observed in obesity. Features of hypogonadism should
be sought (see above) and the tests examined for evidence of
cryptorchidism, atrophy or a tumour.

Investigations

If a clinical distinction between gynaecomastia and adipose
tissue cannot be made, then ultrasonography or mammography
is required. A random blood sample should be taken for
testosterone, LH, FSH, oestradiol, prolactin and hCG. Elevated
oestrogen concentrations are found in testicular tumours and
hCG-producing neoplasms.

Management

An adolescent with gynaecomastia who is progressing normally
through puberty may be reassured that the gynaecomastia will
usually resolve once development is complete. If puberty does not
proceed normally, then there may be an underlying abnormality
that requires investigation (p. 653). Gynaecomastia may cause
significant psychological distress, especially in adolescent boys,
and surgical excision may be justified for cosmetic reasons.
Androgen replacement will usually improve gynaecomastia in
hypogonadal males and any other identifiable underlying cause
should be addressed if possible. The anti-oestrogen tamoxifen
may also be effective in reducing the size of the breast tissue.

Hirsutism

Hirsutism refers to the excessive growth of terminal hair (the thick,
pigmented hair usually associated with the adult male chest) in
an androgen-dependent distribution in women (upper lip, chin,
chest, back, lower abdomen, thigh, forearm) and is one of the
most common presentations of endocrine disease. It should be
distinguished from hypertrichosis, which is generalised excessive
growth of vellus hair (the thin, non-pigmented hair that is typically
found all over the body from childhood onwards). The aetiology of
androgen excess is shown in Box 18.27.

Clinical assessment

The severity of hirsutism is subjective. Some women suffer
profound embarrassment from a degree of hair growth that
others would not consider remarkable. Important observations
are a drug and menstrual history, calculation of body mass index,
measurement of blood pressure, and examination for virilisation
(clitoromegaly, deep voice, male-pattern balding, breast atrophy)
and associated features, including acne vulgaris or Cushing’s
syndrome (p. 666). Hirsutism of recent onset associated with
virilisation is suggestive of an androgen-secreting tumour but
this is rare.

Investigations

A random blood sample should be taken for testosterone,
prolactin, LH and FSH. If there are clinical features of Cushing’s
syndrome, further investigations should be performed (p. 667).
If testosterone levels are more than twice the upper limit of
normal for females, idiopathic hirsutism and PCOS are less
likely, especially if LH and FSH levels are low. Under these

The reproductive system • 657
Women with PCOS are at increased risk of glucose intolerance and some authorities recommend screening for type 2 diabetes and other cardiovascular risk factors associated with the metabolic syndrome (p. 730).

Management
This should be directed at the presenting complaint but all PCOS patients who are overweight should be encouraged to lose weight, as this can improve several symptoms, including menstrual irregularity, and reduces the risk of type 2 diabetes.

### Polycystic ovarian syndrome

Polycystic ovarian syndrome (PCOS) affects up to 10% of women of reproductive age. It is a heterogeneous disorder (Box 18.28), often associated with obesity, for which the primary cause remains uncertain. Genetic factors probably play a role, since PCOS often affects several family members. The severity and clinical features of PCOS vary markedly between individual patients but diagnosis is usually made during the investigation of hirsutism (p. 657) or amenorrhoea/oligomenorrhoea (p. 655). Infertility may also be present (p. 656). There is no universally accepted definition but it has been recommended that a diagnosis of PCOS requires the presence of two of the following three features:

- menstrual irregularity
- clinical or biochemical androgen excess
- multiple cysts in the ovaries (most readily detected by transvaginal ultrasound; Fig. 18.15).

### Causes of hirsutism

*These mechanisms are interrelated; it is not known which, if any, is primary. PCOS probably represents the common endpoint of several different pathologies. (LH = luteinising hormone)

Women with PCOS are at increased risk of glucose intolerance and some authorities recommend screening for type 2 diabetes and other cardiovascular risk factors associated with the metabolic syndrome (p. 730).

Management
This should be directed at the presenting complaint but all PCOS patients who are overweight should be encouraged to lose weight, as this can improve several symptoms, including menstrual irregularity, and reduces the risk of type 2 diabetes.
The reproductive system

Menstrual irregularity and infertility

Most women with PCOS have oligomenorrhea, with irregular, heavy menstrual periods. This may not require treatment unless fertility is desired. Metformin (p. 746), by reducing insulin resistance, may restore regular ovulatory cycles in overweight women, although it is less effective than clomifene (p. 656) at restoring fertility as measured by successful pregnancy. Thiazolidinediones (p. 747) also enhance insulin sensitivity and restore menstrual regularity in PCOS but are contraindicated in women planning pregnancy.

In women who have very few periods each year or are amenorrhoeic, the high oestrogen concentrations associated with PCOS can cause endometrial hyperplasia. Progestogens can be administered on a cyclical basis to induce regular shedding of the endometrium and a withdrawal bleed, or a progestogen-impregnated intrauterine coil can be fitted.

Hirsutism

For hirsutism, most patients will have used cosmetic measures, such as shaving, bleaching and waxing, before consulting a doctor. Electrolysis and laser treatment are effective for small areas like the upper lip and for chest hair but are expensive. Eflornithine cream inhibits ornithine decarboxylase in hair follicles and may reduce hair growth when applied daily to affected areas of the face.

If conservative measures are unsuccessful, anti-androgen therapy is given (Box 18.29). The life cycle of a hair follicle is at least 3 months and no improvement is likely before this time, when follicles have shed their hair and replacement hair growth has been suppressed. Metformin and thiazolidinediones are less effective at treating hirsutism than at restoring menstrual regularity. Unless weight is lost, hirsutism will return if therapy is discontinued. The patient should know that prolonged exposure to some agents may not be desirable and they should be stopped before pregnancy.

Turner’s syndrome

Turner’s syndrome affects around 1 in 2500 females. It is classically associated with a 45XO karyotype but other cytogenetic abnormalities may be responsible, including mosaic forms (e.g. 45XO/46XX or 45XO/46XY) and partial deletions of an X chromosome.

Clinical features

These are shown in Figure 18.16.

Individuals with Turner’s syndrome invariably have short stature from an early age and this is often the initial presenting symptom. It is probably due to haploinsufficiency of the SHOX gene, one copy of which is found on both the X and Y chromosomes, which encodes a protein that is predominantly found in bone fibroblasts.

The genital tract and external genitalia in Turner’s syndrome are female in character, since this is the default developmental outcome in the absence of testes. Ovarian tissue develops normally until the third month of gestation, but thereafter there is gonadal dysgenesis with accelerated degeneration of oocytes and increased ovarian stromal fibrosis, resulting in ‘streak ovaries’. The inability of ovarian tissue to produce oestrogen results in loss of negative feedback and elevation of FSH and LH concentrations.

There is a wide variation in the spectrum of associated somatic abnormalities. The severity of the phenotype is, in part, related to

**Fig. 18.15 Polycystic ovary.** A transvaginal ultrasound scan showing multiple cysts (some indicated by small arrows) in the ovary (highlighted by bigger arrows) of a woman with polycystic ovarian syndrome.
Clinical features
The diagnosis is typically made in adolescents who have presented with gynaecomastia and failure to progress normally through puberty. Affected individuals usually have small, firm testes. Tall stature is apparent from early childhood, reflecting characteristically long leg length associated with 47XXY, and may be exacerbated by androgen deficiency with lack of epiphyseal closure in puberty. Other clinical features may include learning difficulties and behavioural disorders, as well as an increased risk of breast cancer and type 2 diabetes in later life. The spectrum of clinical features is wide and some individuals, especially those with the underlying cytogenetic abnormality. Mosaic individuals may have only mild short stature and may enter puberty spontaneously before developing gonadal failure.

**Diagnosis and management**

The diagnosis of Turner’s syndrome can be confirmed by karyotype analysis. Short stature, although not directly due to growth hormone deficiency, responds to high doses of growth hormone. Prophylactic gonadectomy is recommended for individuals with 45XO/46XY mosaicism because there is an increased risk of gonadoblastoma. Pubertal development can be induced with oestrogen therapy but causes fusion of the epiphyses and cessation of growth. The timing of pubertal induction therefore needs to be carefully planned. Adults with Turner’s syndrome require long-term oestrogen replacement therapy and should be monitored periodically for the development of aortic root dilatation, hearing loss and other somatic complications.

**Klinefelter’s syndrome**

Klinefelter’s syndrome affects approximately 1 in 1000 males and is usually associated with a 47XXY karyotype. However, other cytogenetic variants may be responsible, especially 46XY/47XXY mosaicism. The principal pathological abnormality is dysgenesis of the seminiferous tubules. This is evident from infancy (and possibly even in utero) and progresses with age. By adolescence, hyalination and fibrosis are present within the seminiferous tubules and Leydig cell function is impaired, resulting in hypogonadism.

**Psychological problems**
- Impaired visuospatial processing
- Reduced IQ (ring chromosome X)

**Physical features**
- Low-set ears
- Sensorineural/conduction hearing loss
- Webbing of neck (25–40%)
- Widely spaced nipples
- Shield chest
- Wide carrying angle of elbows

**Endocrine features**
- Type 2 diabetes/IGT (10–30%)
- Inflammatory bowel disease (0.2–0.3%)
- Horseshoe kidneys and other renal and collecting system abnormalities
- Reduced bone mineral density

**Fig. 18.16 Clinical features of Turner’s syndrome (45X0).** (IGT = impaired glucose tolerance; LFTs = liver function tests)

**18.30 Gonadal function in old age**

- **Post-menopausal osteoporosis**: a major public health issue due to the high incidence of associated fragility fractures, especially of hip.
- **Hormone replacement therapy**: should be prescribed only above the age of 50 for the short-term relief of symptoms of oestrogen deficiency.
- **Sexual activity**: many older people remain sexually active.
- **‘Male menopause’**: does not occur, although testosterone concentrations do fall with age. Testosterone therapy in mildly hypogonadal men may be of benefit for body composition, muscle and bone. Large randomised trials are required to determine whether benefits outweigh potentially harmful effects on the prostate and cardiovascular system.
- **Androgens in older women**: hirsutism and balding occur. In those rare patients with elevated androgen levels, this may be pathological, e.g. from an ovarian tumour.

**Clinical features**

The diagnosis is typically made in adolescents who have presented with gynaecomastia and failure to progress normally through puberty. Affected individuals usually have small, firm testes. Tall stature is apparent from early childhood, reflecting characteristically long leg length associated with 47XXY, and may be exacerbated by androgen deficiency with lack of epiphyseal closure in puberty. Other clinical features may include learning difficulties and behavioural disorders, as well as an increased risk of breast cancer and type 2 diabetes in later life. The spectrum of clinical features is wide and some individuals, especially...
The parathyroid glands

Parathyroid hormone (PTH) plays a key role in the regulation of calcium and phosphate homeostasis and vitamin D metabolism, as shown in Figure 24.61 (p. 1051). The consequences of altered function of this axis in gut and renal disease are covered on pages 783 and 418, respectively. Other metabolic bone diseases are explored on page 1044. Here, the investigation of hypercalcaemia and hypocalcaemia and disorders of the parathyroid glands are discussed.

Functional anatomy, physiology and investigations

The four parathyroid glands lie behind the lobes of the thyroid and weigh between 25 and 40 mg. The parathyroid chief cells respond directly to changes in calcium concentrations via a G protein-coupled cell surface receptor (the calcium-sensing receptor) located on the cell surface (see Fig. 25.55). When serum ionised calcium levels fall, PTH secretion rises. PTH is a single-chain polypeptide of 84 amino acids. It acts on the renal tubules to promote reabsorption of calcium and reduce reabsorption of phosphate, and on the skeleton to increase osteoclastic bone resorption and bone formation. PTH also promotes the conversion of 25-hydroxyvitamin D to the active metabolite, 1,25-dihydroxyvitamin D; the 1,25-dihydroxyvitamin D, in turn, enhances calcium absorption from the gut.

More than 99% of total body calcium is in bone. Prolonged exposure of bone to high levels of PTH is associated with increased osteoclastic activity and new bone formation, but the net effect is to cause bone loss with mobilisation of calcium into the extracellular fluid. In contrast, pulsatile release of PTH causes net bone gain, an effect that is exploited therapeutically in the treatment of osteoporosis (p. 1048).

The differential diagnosis of disorders of calcium metabolism requires measurement of calcium phosphate, alkaline phosphatase, renal function, PTH and 25-hydroxyvitamin D. Although the parathyroid glands detect and respond to ionised calcium levels, most clinical laboratories measure only total serum calcium levels. About 50% of total calcium is bound to organic ions, such as citrate or phosphate, and to proteins, especially albumin. Accordingly, if the serum albumin level is reduced, total calcium concentrations should be corrected by adjusting the value for calcium upwards by 0.02 mmol/L (0.08 mg/dL) for each 1 g/L reduction in albumin below 40 g/L. If albumin concentrations are significantly low, as in severe acute illness and other chronic illness such as liver cirrhosis, this correction is less accurate and measurement of ionised calcium is needed.

Calcitonin is secreted from the parafollicular C cells of the thyroid gland. Although it is a useful tumour marker in medullary carcinoma of thyroid (p. 650) and can be given therapeutically in Paget’s disease of bone (p. 1053), its release from the thyroid is of no clinical relevance to calcium homeostasis in humans.

Disorders of the parathyroid glands are summarised in Box 18.31.

### Presenting problems in parathyroid disease

#### Hypercalcaemia

Hypercalcaemia is one of the most common biochemical abnormalities and is often detected during routine biochemical analysis in asymptomatic patients. However, it can present with chronic symptoms, as described below, and occasionally as an acute emergency with severe hypercalcaemia and dehydration.

---

1Parathyroid carcinomas may or may not produce parathyroid hormone. 2In multiple endocrine neoplasia (MEN) syndromes (p. 688). (CASR = calcium-sensing receptor)
Causes of hypercalcaemia are listed in Box 18.32. Of these, primary hyperparathyroidism and malignant hypercalcaemia are by far the most common. Familial hypocalciuric hypercalcaemia (FHH) is a rare but important cause that needs differentiation from primary hyperparathyroidism (HPT). Lithium may cause hyperparathyroidism by reducing the sensitivity of the calcium-sensing receptor.

**Clinical assessment**

Symptoms and signs of hypercalcaemia include polyuria and polydipsia, renal colic, lethargy, anorexia, nausea, dyspepsia and peptic ulceration, constipation, depression, drowsiness and impaired cognition. Patients with malignant hypercalcaemia can have a rapid onset of symptoms and may have clinical features that help to localise the tumour.

The classic symptoms of primary hyperparathyroidism are described by the adage ‘bones, stones and abdominal groans’, but few patients present in this way nowadays and the disorder is most often picked up as an incidental finding on biochemical testing. About 50% of patients with primary hyperparathyroidism are asymptomatic while others have non-specific symptoms such as fatigue, depression and generalised aches and pains. Some present with renal calculi and it has been estimated that 5% of first stone formers and 15% of recurrent stone formers have primary hyperparathyroidism (p. 663). Hypertension is a common feature of hyperparathyroidism. Parathyroid tumours are almost never palpable.

A family history of hypercalcaemia raises the possibility of FHH or MEN (p. 688).

**Investigations**

The most discriminatory investigation is measurement of PTH. If PTH levels are detectable or elevated in the presence of hypercalcaemia, then primary hyperparathyroidism is the most likely diagnosis. High plasma phosphate and alkaline phosphatase accompanied by renal impairment suggest tertiary hyperparathyroidism. Hypercalcaemia may cause nephrocalcinosis and renal tubular impairment, resulting in hyperuricaemia and hyperchloraemia.

Patients with FHH can present with a similar biochemical picture to primary hyperparathyroidism but typically have low urinary calcium excretion (a ratio of urinary calcium clearance to creatinine clearance of <0.01). The diagnosis of FHH can be confirmed by screening family members for hypercalcaemia and/or identifying an inactivating mutation in the gene encoding the calcium-sensing receptor.

If PTH is low and no other cause is apparent, then malignancy with or without bony metastases is likely. PTH-related peptide, which is often responsible for the hypercalcaemia associated with malignancy, is not detected by PTH assays, but can be measured by a specific assay (although this is not usually necessary). Unless the source is obvious, the patient should be screened for malignancy with a chest X-ray, myeloma screen (p. 967) and CT as appropriate.

**Management**

Treatment of severe hypercalcaemia and primary hyperparathyroidism is described on pages 663 and 1327, respectively. FHH does not require any specific intervention.

---

### 18.32 Causes of hypercalcaemia

**With normal or elevated parathyroid hormone (PTH) levels**

- Primary or tertiary hyperparathyroidism
- Lithium-induced hyperparathyroidism
- Familial hypocalciuric hypercalcaemia

**With low PTH levels**

- Malignancy (lung, breast, myeloma, renal, lymphoma, thyroid)
- Elevated 1,25-dihydroxyvitamin D (vitamin D intoxication, sarcoidosis, human immunodeficiency virus, other granulomatous disease)
- Thyrotoxicosis
- Paget’s disease with immobilisation
- Milk-alkali syndrome
- Thiazide diuretics
- Glucocorticoid deficiency

(↑ = levels increased; ↓ = levels reduced; ↔ = levels normal)
cause of hypocalcaemia is a low serum albumin with normal ionised calcium concentration. Conversely, ionised calcium may be low in the face of normal total serum calcium in patients with alkalosis: for example, as a result of hyperventilation.

Hypocalcaemia may also develop as a result of magnesium depletion and should be considered in patients with malabsorption, those on diuretic or proton pump inhibitor therapy, and/or those with a history of alcohol excess. Magnesium deficiency causes hypocalcaemia by impairing the ability of the parathyroid glands to secrete PTH (resulting in PTH concentrations that are low or inappropriately in the reference range) and may also impair the actions of PTH on bone and kidney.

**Clinical assessment**

Mild hypocalcaemia is often asymptomatic but, with more profound reductions in serum calcium, tetany can occur. This is characterised by muscle spasms due to increased excitability of peripheral nerves.

Children are more liable to develop tetany than adults and present with a characteristic triad of carpopedal spasm, stridor and convulsions, although one or more of these may be found independently of the others. In carpopedal spasm, the hands adopt a characteristic position with flexion of the metacarpophalangeal joints of the fingers and adduction of the thumb (‘main d’accoucheur’). Pedal spasm can also occur but is less frequent. Stridor is caused by spasm of the glottis. Adults can also develop carpopedal spasm in association with tingling of the hands and feet around the mouth, but stridor and fits are rare.

Latent tetany may be detected by eliciting Trousseau’s sign: inflation of a sphygmomanometer cuff on the upper arm to more than the systolic blood pressure is followed by carpal spasm within 3 minutes. Less specific is Chvostek’s sign, in which tapping over the branches of the facial nerve as they emerge from the parotid glands produces twitching of the facial muscles.

Hypocalcaemia can cause papilloedema and prolongation of the ECG QT interval, which may predispose to ventricular arrhythmias. Prolonged hypocalcaemia and hyperphosphataemia (as in hypoparathyroidism) may cause calcification of the basal ganglia, grand mal epilepsy, psychosis and cataracts. Hypocalcaemia associated with hyperphosphataemia, as in vitamin D deficiency, causes rickets in children and osteomalacia in adults (p. 1049).

**Management**

Emergency management of hypocalcaemia associated with tetany is given in Box 18.34. Treatment of chronic hypocalcaemia is described on page 1051.

### 18.34 Management of severe hypocalcaemia

**Immediate management**

- 10–20 mL 10% calcium gluconate IV over 10–20 mins
- Continuous IV infusion may be required for several hours (equivalent of 10 mL 10% calcium gluconate/hr)
- Cardiac monitoring is recommended

**If associated with hypomagnesaemia**

- 50 mmol (1.23 g) magnesium chloride IV over 24 hrs
- Most parental magnesium will be excreted in the urine, so further doses may be required to replenish body stores

### Primary hyperparathyroidism

Primary hyperparathyroidism is caused by autonomous secretion of PTH, usually by a single parathyroid adenoma, which can vary in diameter from a few millimetres to several centimetres. It should be distinguished from secondary hyperparathyroidism, in which there is a physiological increase in PTH secretion to compensate for prolonged hypocalcaemia (such as in vitamin D deficiency, p. 1049), and from tertiary hyperparathyroidism, in which continuous stimulation of the parathyroids over a prolonged period of time results in adenoma formation and autonomous PTH secretion (Box 18.35). This is most commonly seen in individuals with advanced chronic kidney disease (p. 418).

The prevalence of primary hyperparathyroidism is about 1 in 800 and it is 2–3 times more common in women than men; 90% of patients are over 50 years of age. It also occurs in the familial MEN syndromes (p. 688), in which case hyperplasia or multiple adenomas of all four parathyroid glands are more likely than a solitary adenoma.

**Clinical and radiological features**

The clinical presentation of primary hyperparathyroidism is described on page 667. Parathyroid bone disease is now rare due to earlier diagnosis and treatment. Osteitis fibrosa results from increased bone resorption by osteoclasts with fibrous replacement in the lacunae. This may present as bone pain and tenderness, fracture and deformity. Chondrocalcinosis can occur due to deposition of calcium pyrophosphate crystals within articular cartilage. It typically affects the menisci at the knees and can result in secondary degenerative arthritis or predispose to attacks of acute pseudogout (p. 1016). Skeletal X-rays are usually normal in mild primary hyperparathyroidism, but in patients with advanced disease characteristic changes are observed. In the early stages there is demineralisation, with subperiosteal erosions and terminal resorption in the phalanges. A ‘pepper-pot’ appearance may be seen on lateral X-rays of the skull. Reduced bone mineral density, resulting in either osteopenia or osteoporosis, is now the most common skeletal manifestation of hyperparathyroidism. This is usually not evident radiographically and requires assessment by DEXA (p. 989).

In nephrocalcinosis, scattered opacities may be visible within the renal outline. There may be soft tissue calcification in arterial walls and hands and in the cornea.

**Investigations**

The diagnosis can be confirmed by finding a raised PTH level in the presence of hypercalcaemia, provided that FHH is excluded.

(p. 664). Parathyroid scanning by \(^{99m}\)Tc-sestamibi scintigraphy (MIBI; Fig. 18.17) and an ultrasound examination can be performed prior to surgery, in an attempt to localise an adenoma; a concordant finding of tissue consistent with a parathyroid gland and uptake on the MIBI scan allows a targeted resection. Negative imaging does not exclude the diagnosis, however, and four-gland exploration may be needed.

**Management**

The treatment of choice for primary hyperparathyroidism is surgery, with excision of a solitary parathyroid adenoma or hyperplastic glands. Experienced surgeons will identify solitary tumours in more than 90% of cases. Patients with parathyroid bone disease run a significant risk of developing hypocalcaemia post-operatively but the risk of this can be reduced by correcting vitamin D deficiency pre-operatively.

Surgery is usually indicated for individuals aged less than 50 years, with clear-cut symptoms or documented complications (such as renal stones, renal impairment or osteoporosis), and (in asymptomatic patients) significant hypercalcaemia (corrected serum calcium >2.85 mmol/L (>11.4 mg/dL)). Patients who are treated conservatively without surgery should have calcium biochemistry and renal function checked annually and bone density monitored periodically. They should be encouraged to maintain a high oral fluid intake to avoid renal stones.

Occasionally, primary hyperparathyroidism presents with severe life-threatening hypercalcaemia. This is often due to dehydration and should be managed medically with intravenous fluids and bisphosphonates, as described on page 1327. If this is not effective, then urgent parathyroidectomy should be considered.

Cinacalcet (p. 419) is a calcimimetic that enhances the sensitivity of the calcium-sensing receptor, so reducing PTH levels, and is licensed for tertiary hyperparathyroidism and as a treatment for patients with primary hyperparathyroidism who are unwilling to have surgery or are medically unfit.

**Familial hypocalciuric hypercalcaemia**

This autosomal dominant disorder is caused by an inactivating mutation in one of the alleles of the calcium-sensing receptor gene, which reduces the ability of the parathyroid gland to ‘sense’ ionised calcium concentrations. As a result, higher than normal calcium levels are required to suppress PTH secretion. The typical presentation is with mild hypercalcaemia with PTH concentrations that are ‘inappropriately’ at the upper end of the reference range or are slightly elevated. Calcium-sensing receptors in the renal tubules are also affected and this leads to increased renal tubular reabsorption of calcium and hypocalciuria (as measured in the vitamin D-replete individual by a fractional calcium excretion or 24-hour calcium excretion). The hypercalcaemia of FHH is always asymptomatic and complications do not occur. The main risk of FHH is that of the patient being subjected to an unnecessary (and ineffective) parathyroidectomy if misdiagnosed as having primary hyperparathyroidism. Testing of family members for hypocalcaemia is helpful in confirming the diagnosis and it is also possible to perform genetic testing. No treatment is necessary.

**Hypoparathyroidism**

The most common cause of hypoparathyroidism is damage to the parathyroid glands (or their blood supply) during thyroid surgery. Rarely, hypoparathyroidism can occur as a result of infiltration of the glands with iron in haemochromatosis (p. 895) or copper in Wilson’s disease (p. 896).

There are a number of rare congenital or inherited forms of hypoparathyroidism. One form is associated with autoimmune polyendocrine syndrome type 1 (p. 689) and another with DiGeorge syndrome (p. 79). Autosomal dominant hypoparathyroidism is the mirror image of FHH (see above), in that an activating mutation in the calcium-sensing receptor reduces PTH levels, resulting in hypocalcaemia and hypercalciuria.

**Pseudohypoparathyroidism**

In this disorder, the individual is functionally hypoparathyroid but, instead of PTH deficiency, there is tissue resistance to the effects of PTH, such that PTH concentrations are markedly elevated. The PTH receptor itself is normal but the downstream signalling pathways are defective due to mutations that affect GNAS1, which encodes the Gs protein, a molecule involved in signal transduction downstream of the PTH receptor and other G protein-coupled receptors. There are several subtypes but the most common (pseudohypoparathyroidism type 1a) is characterised by hypocalcaemia and hyperphosphataemia, in association with short stature, short fourth metacarpals and metatarsals, rounded face, obesity and subcutaneous calcification; these features are collectively referred to as Albright’s hereditary osteodystrophy (AHO). Type 1a pseudohypoparathyroidism occurs only when the GNAS1 mutation is inherited on the maternal chromosome (maternal imprinting, p. 49).

The term pseudopseudohypoparathyroidism is used to describe patients who have clinical features of AHO but normal serum calcium and PTH concentrations; it occurs when the GNAS1 mutation is inherited on the paternal chromosome. The inheritance of these disorders is an example of genetic imprinting (p. 49). The difference in clinical features occurs as a result of the fact that renal cells exclusively express the maternal GNAS1 allele, whereas both maternal and paternal alleles are expressed in other cell types; this explains why maternal inheritance is associated with hypocalcaemia and resistance to PTH (which regulates
serum calcium and phosphate levels largely by an effect on the renal tubule), and why paternal inheritance is associated with skeletal and other abnormalities in the absence of hypocalcaemia and raised PTH values.

**Management of hypoparathyroidism**

Persistent hypoparathyroidism and pseudohypoparathyroidism are treated with oral calcium salts and vitamin D analogues, either 1α-hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). This therapy needs careful monitoring because of the risks of iatrogenic hypercalcemia, hypercalciuria and nephrocalcinosis. Recombinant PTH is available as subcutaneous injection therapy for osteoporosis (p. 1048) and, although not currently licensed, has been used in hypoparathyroidism (but not in pseudohypoparathyroidism). It is much more expensive than calcium and vitamin D analogue therapy but has the advantage that it is less likely to cause hypercalciuria. There is no specific treatment for AHO other than therapy but has the advantage that it is less likely to cause hypercalciuria. There is no specific treatment for AHO other than

Adrenergic therapy is much more expensive than calcium and vitamin D analogue therapy but has the advantage that it is less likely to cause hypercalciuria. There is no specific treatment for AHO other than

There is increasing evidence that subtle alterations in adrenal function contribute to the pathogenesis of common diseases such as hypertension, obesity and type 2 diabetes mellitus. However, classical syndromes of adrenal hormone deficiency and excess are relatively rare.

**Functional anatomy and physiology**

Adrenal anatomy and function are shown in Figure 18.18. Histologically, the cortex is divided into three zones, but these function as two units (zona glomerulosa and zona fasciculata/reticularis) that produce corticosteroids in response to humoral stimuli. Pathways for the biosynthesis of corticosteroids are shown in Figure 18.19. Investigation of adrenal function is described under specific diseases below. The different types of adrenal disease are shown in Box 18.37.

**Glucocorticoids**

Cortisol is the major glucocorticoid in humans. Levels are highest in the morning on waking and lowest in the middle of the night. Cortisol rises dramatically during stress, including any illness. This elevation protects key metabolic functions (such as the maintenance of cerebral glucose supply during starvation) and inhibits potentially damaging inflammatory responses to infection and injury. The clinical importance of cortisol deficiency is, therefore, most obvious at times of stress.

More than 95% of circulating cortisol is bound to protein, principally cortisol-binding globulin, which is increased by oestrogens. It is the free fraction that is biologically active. Cortisol regulates cell function by binding to glucocorticoid receptors that regulate the transcription of many genes. Cortisol could also activate mineralocorticoid receptors, but it does not normally do so because most cells containing mineralocorticoid receptors also express an enzyme called 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which inactivates cortisol by converting it to cortisone. Inhibitors of 11β-HSD2 (such as liquorice) or mutations in the gene that encodes 11β-HSD2 cause cortisol to act as a mineralocorticoid, resulting in sodium retention and hypertension (see Box 18.46).
Mineralocorticoids

Aldosterone is the most important mineralocorticoid. It binds to mineralocorticoid receptors in the kidney and causes sodium retention and increased excretion of potassium and protons (p. 351). The principal stimulus to aldosterone secretion is angiotensin II, a peptide produced by activation of the renin–angiotensin system (see Fig. 18.18). Renin activity in the juxtaglomerular apparatus of the kidney is stimulated by low perfusion pressure in the afferent arteriole, low sodium filtration leading to low sodium concentrations at the macula densa, or increased sympathetic nerve activity. As a result, renin activity is increased in hypovolaemia and renal artery stenosis, and is approximately doubled when standing up from a recumbent position.

Catecholamines

In humans, only a small proportion of circulating noradrenaline (norepinephrine) is derived from the adrenal medulla; much more is released from sympathetic nerve endings. Conversion of noradrenaline to adrenaline (epinephrine) is catalysed by catechol O-methyltransferase (COMT), which is induced by glucocorticoids. Blood flow in the adrenal is centripetal, so that the medulla is bathed in high concentrations of cortisol and is the major source of circulating adrenaline. However, after surgical removal of the adrenal medullae, there appear to be no clinical consequences attributable to deficiency of circulating catecholamines.

Adrenal androgens

Adrenal androgens are secreted in response to ACTH and are the most abundant steroids in the blood stream. They are probably important in the initiation of puberty (adrenarche). The adrenals are also the major source of androgens in adult females and may be important in female libido.

Presenting problems in adrenal disease

Cushing’s syndrome

Cushing’s syndrome is caused by excessive activation of glucocorticoid receptors. It is most commonly iatrogenic, due to prolonged administration of synthetic glucocorticoids such as
Endogenous Cushing’s syndrome is uncommon but is caused by chronic over-production of cortisol by the adrenal glands, either as the result of an adrenal tumour or because of excessive production of ACTH by a pituitary tumour or ectopic ACTH production by other tumours.

**Aetiology**

The causes are shown in Box 18.38. Amongst endogenous causes, pituitary-dependent cortisol excess (by convention, called Cushing’s disease) accounts for approximately 80% of cases. Both Cushing’s disease and cortisol-secreting adrenal tumours are four times more common in women than men. In contrast, ectopic ACTH syndrome (often due to a small-cell carcinoma of the bronchus) is more common in men.

**Clinical assessment**

The diverse manifestations of glucocorticoid excess are shown in Figure 18.20. Many of these are not specific to Cushing’s syndrome and, because spontaneous Cushing’s syndrome is rare, the positive predictive value of any single clinical feature alone is low. Moreover, some common disorders can be confused with Cushing’s syndrome because they are associated with alterations in cortisol secretion, e.g. obesity and depression (Box 18.38). Features that favour Cushing’s syndrome in an obese patient are bruising, myopathy and thin skin. Any clinical suspicion of Cushing’s syndrome because they are associated with alterations in cortisol secretion, e.g. obesity and depression (Box 18.38). Features that favour Cushing’s syndrome in an obese patient are bruising, myopathy and thin skin. Any clinical suspicion of Cushing’s syndrome is best resolved by further investigation.

Investigations

The large number of tests available for Cushing’s syndrome reflects the fact that each one has limited specificity and sensitivity.

---

**Fig. 18.19** The major pathways of synthesis of steroid hormones. (DHEAS = dehydroepiandrosterone sulphate; HSD = hydroxysteroid dehydrogenase)
measured following administration of 0.5 mg dexamethasone 4 times daily for 48 hours. For either test, a normal response is a serum cortisol of < 50 nmol/L (1.8 μg/dL). It is important for any oestrogens to be stopped for 6 weeks prior to investigation to allow corticosteroid-binding globulin (CBG) levels to return to normal and to avoid false-positive responses, as most cortisol assays measure total cortisol, including that bound to CBG.

Cyclicity of cortisol secretion is a feature of all types of Cushing’s syndrome and, if very variable, can confuse diagnosis. Use of multiple salivary cortisol samples over weeks or months can be helpful in diagnosis but an elevated salivary cortisol alone should not be taken as proof of diagnosis. In iatrogenic Cushing’s syndrome, cortisol levels are low unless the patient is taking a glucocorticoid (such as prednisolone) that cross-reacts in immunoassays with cortisol.

Determining the underlying cause

Once the presence of Cushing’s syndrome is confirmed, measurement of plasma ACTH is the key to establishing the differential diagnosis; it is best measured in the morning around 0900 hrs. In the presence of excess cortisol secretion, an undetectable ACTH (< 1.1 pmol/L (5 ng/L)) indicates an adrenal cause, while ACTH levels of > 3.3 pmol/L (15 ng/L) suggest a pituitary cause or ectopic ACTH. ACTH levels between these values represent a ‘grey area’ and further evaluation by a specialist is required. Tests to discriminate pituitary from ectopic sources of ACTH rely on the fact that pituitary tumours, but not ectopic tumours, retain some features of normal regulation of
The adrenal glands

ACTH secretion. Thus, in pituitary-dependent Cushing’s disease, ACTH secretion is suppressed by high-dose dexamethasone and ACTH is stimulated by corticotropin-releasing hormone (CRH). In a high-dose dexamethasone suppression test (HDDST), serum cortisol is measured before and after administration of 2 mg of dexamethasone 4 times daily for 48 hours.

Techniques for localisation of tumours secreting ACTH or cortisol are listed in Figure 18.22. MRI detects around 60% of pituitary microadenomas secreting ACTH. If available, bilateral inferior petrosal sinus sampling (BIPSS) with measurement of ACTH is the best means of confirming Cushing’s disease, unless MRI shows a tumour bigger than 6 mm, in which case it may not be needed. CT or MRI detects most adrenal tumours; adrenal carcinomas are usually large (>5 cm) and have other features of malignancy (p. 673).

Management

Untreated severe Cushing’s syndrome has a 50% 5-year mortality. Most patients are treated surgically, but medical therapy may be given in severe cases for a few weeks prior to operation to improve the clinical state. A number of drugs are available that inhibit glucocorticoid biosynthesis, including metyrapone and ketoconazole. The dose of these agents is best titrated against serum cortisol levels or 24-hour urine free cortisol.

Cushing’s syndrome suspected

Exclude exogenous glucocorticoid exposure

Perform one of the following tests

- 24-UFC (≥ 2 tests)
  - Elevated if above reference range for assay

- ONDST or LDDST
  - Abnormal if serum cortisol > 50 nmol/L

- Late-night salivary cortisol
  - Abnormal if above local reference range

Any abnormal result

Perform 1 or 2 other studies shown above and consider repeating abnormal study

Discrepant test results

Suggest additional evaluation, repeat testing at interval or seek further opinion

At least two concordant abnormal tests

ACTH secretion. Thus, in pituitary-dependent Cushing’s disease, ACTH secretion is suppressed by high-dose dexamethasone and ACTH is stimulated by corticotropin-releasing hormone (CRH). In a high-dose dexamethasone suppression test (HDDST), serum cortisol is measured before and after administration of 2 mg of dexamethasone 4 times daily for 48 hours.

Techniques for localisation of tumours secreting ACTH or cortisol are listed in Figure 18.22. MRI detects around 60% of pituitary microadenomas secreting ACTH. If available, bilateral inferior petrosal sinus sampling (BIPSS) with measurement of ACTH is the best means of confirming Cushing’s disease, unless MRI shows a tumour bigger than 6 mm, in which case it may not be needed. CT or MRI detects most adrenal tumours; adrenal carcinomas are usually large (>5 cm) and have other features of malignancy (p. 673).

Management

Untreated severe Cushing’s syndrome has a 50% 5-year mortality. Most patients are treated surgically, but medical therapy may be given in severe cases for a few weeks prior to operation to improve the clinical state. A number of drugs are available that inhibit glucocorticoid biosynthesis, including metyrapone and ketoconazole. The dose of these agents is best titrated against serum cortisol levels or 24-hour urine free cortisol.

Cushing’s disease

Trans-sphenoidal surgery carried out by an experienced surgeon with selective removal of the adenoma is the treatment of choice, with approximately 70% of patients going into immediate remission. Around 20% of patients suffer a recurrence, often years later, emphasising the need for life-long follow-up.

Laparoscopic bilateral adrenalectomy performed by an expert surgeon effectively cures ACTH-dependent Cushing’s syndrome, but in patients with pituitary-dependent Cushing’s syndrome this can result in Nelson’s syndrome. In Nelson’s syndrome, the loss of negative feedback from endogenous cortisol results in growth of the pituitary tumour, often leading to an invasive pituitary macroadenoma (which causes local mass effects) and very high ACTH levels (which cause pigmentation). The risk of Nelson’s syndrome is reported as being reduced by pituitary irradiation in some series, but not all.

The somatostatin analogue pasireotide is also licensed for the treatment of Cushing’s disease and works by suppressing ACTH secretion by the tumour. It may cause tumour shrinkage but cortisol levels are likely to return to pre-treatment levels following cessation of therapy. Pasireotide has to be administered by twice-daily subcutaneous injection and is relatively expensive. It is an alternative to drugs that inhibit glucocorticoid biosynthesis in patients who are not suitable for a surgical approach.

Adrenal tumours

Laparoscopic adrenal surgery is the treatment of choice for adrenal adenomas. Surgery offers the only prospect of cure for adrenocortical carcinomas but, in general, prognosis is poor with high rates of recurrence, even in patients with localised disease at presentation. Radiotherapy to the tumour bed reduces
Adverse effects of glucocorticoids

The clinical features of glucocorticoid excess are illustrated in Figure 18.20. Adverse effects are related to dose, duration of therapy, and pre-existing conditions that might be worsened by glucocorticoid therapy, such as diabetes mellitus or osteoporosis. Osteoporosis is a particularly important problem because, for a given bone mineral density, the fracture risk is greater in glucocorticoid-treated patients than in post-menopausal osteoporosis. Therefore, when systemic glucocorticoids are prescribed and the anticipated duration of steroid therapy is more than 3 months, bone-protective therapy should be considered, as detailed on page 1005. Rapid changes in glucocorticoid levels can also lead to marked mood disturbances, including depression, mania and insomnia. Glucocorticoid use also increases the white blood cell count (predominantly neutrophils), which must be taken into account when assessing patients with possible infection.

Ectopic ACTH syndrome

Localised tumours, such as bronchial carcinoid, should be removed surgically. In patients with incurable malignancy, it is important to reduce the severity of the Cushing’s syndrome using medical therapy (see above) or, if appropriate, bilateral adrenalectomy.

Therapeutic use of glucocorticoids

The remarkable anti-inflammatory properties of glucocorticoids have led to their use in a wide variety of clinical conditions but the hazards are significant. Equivalent doses of commonly used glucocorticoids are listed in Box 18.39. Topical preparations (dermal, rectal and inhaled) can also be absorbed into the systemic circulation, and although this rarely occurs to a sufficient degree to produce clinical features of Cushing’s syndrome, it can result in significant suppression of endogenous ACTH and cortisol secretion. Severe Cushing’s syndrome can result if there is concomitant administration of inhaled glucocorticoids and strong inhibitors of the liver enzyme CYP450 3A4, such as the antiretroviral drug ritonavir (p. 324).

Fig. 18.22 Determining the cause of confirmed Cushing’s syndrome. To convert pmol/L to ng/L, multiply by 4.541. (ACTH = adrenocorticotropic hormone; AIMAH = ACTH-independent macronodular adrenal hyperplasia; BIPSS = bilateral inferior petrosal sinus sampling; hCRH = human corticotrophin-releasing hormone; HDDST = high-dose dexamethasone suppression test; PPNAD = primary pigmented nodular adrenal disease)
The anti-inflammatory effect of glucocorticoids may mask signs of disease. For example, perforation of a viscus may be masked and the patient may show no febrile response to an infection. Although there is debate about whether or not glucocorticoids increase the risk of peptic ulcer when used alone, they act synergistically with NSAIDs, including aspirin, to increase the risk of serious gastrointestinal adverse effects. Latent tuberculosis may be reactivated and patients on glucocorticoids are at risk of severe varicella zoster virus infection, so should avoid contact with chickenpox or shingles if they are non-immune.

**Management of glucocorticoid withdrawal**

All glucocorticoid therapy, even if inhaled or applied topically, can suppress the HPA axis. In practice, this is likely to result in a crisis due to adrenal insufficiency on withdrawal of treatment only if glucocorticoids have been administered orally or systemically for longer than 3 weeks, if repeated courses have been prescribed within the previous year, or if the dose is higher than the equivalent of 7.5 mg prednisolone per day. In these circumstances, the drug, when it is no longer required for the underlying condition, must be withdrawn slowly at a rate dictated by the duration of treatment. If glucocorticoid therapy has been prolonged, then it may take many months for the HPA axis to recover. All patients must be advised to avoid sudden drug withdrawal. They should be issued with a steroid card and/or wear an engraved bracelet (Box 18.40).

Recovery of the HPA axis is aided if there is no exogenous glucocorticoid present during the nocturnal surge in ACTH secretion. This can be achieved by giving glucocorticoid in the morning. Giving ACTH to stimulate adrenal recovery is of no value, as the pituitary remains suppressed.

In patients who have received glucocorticoids for longer than a few weeks, especially if the period is months to years, it is often valuable to confirm that the HPA axis is recovering during glucocorticoid withdrawal. Withdrawal has to be very slow, usually by a dose reduction equivalent of prednisolone 1 mg per month or slower. Once the dose of glucocorticoid is reduced to a minimum (e.g. 5 mg prednisolone or 0.5 mg dexamethasone per day), then serum cortisol can be measured at 0900 hrs before the next dose. If this is <100 nmol/L (3.6 μg/dL), slow reduction should be continued with a repeat 0900 hrs serum cortisol when the dose of prednisolone is 3 mg per day. Once 0900 hrs serum cortisol is >100 nmol/L, then an ACTH stimulation test should be performed (see Box 18.43) to confirm if glucocorticoids can be withdrawn completely. Even when glucocorticoids have been successfully withdrawn, short-term replacement therapy is often advised during significant intercurrent illness occurring in subsequent months, as the HPA axis may not be able to respond fully to severe stress.

### Adrenal insufficiency

Adrenal insufficiency results from inadequate secretion of cortisol and/or aldosterone. It is potentially fatal and notoriously variable in its presentation. A high index of suspicion is therefore required in patients with unexplained fatigue, hyponatraemia or hypotension. Causes are shown in Box 18.41. The most common is ACTH deficiency (secondary adrenocortical failure), usually because of inappropriate withdrawal of chronic glucocorticoid therapy or a pituitary tumour (p. 683). Congenital adrenal hyperplasia and Addison’s disease (primary adrenocortical failure) are rare causes.

#### Clinical assessment

The clinical features of adrenal insufficiency are shown in Box 18.42. In Addison’s disease, either glucocorticoid or mineralocorticoid deficiency may come first, but eventually all patients fail to secrete both classes of corticosteroid.

Patients may present with chronic features and/or in acute circulatory shock. With a chronic presentation, initial symptoms are often misdiagnosed as chronic fatigue syndrome or depression. In primary adrenal insufficiency, weight loss is a uniform presenting feature. Adrenocortical insufficiency should also be considered in patients with hyponatraemia, even in the absence of symptoms (p. 357).

Features of an acute adrenal crisis include circulatory shock with severe hypotension, hyponatraemia, hyperkalaemia and, in some instances, hypoglycaemia and hypercalcaemia. Muscle cramps, nausea, vomiting, diarrhoea and unexplained fever...
Assessment of glucocorticoids

Random plasma cortisol is usually low in patients with adrenal insufficiency but it may be within the reference range, yet inappropriately low, for a seriously ill patient. Random measurement of normal levels of plasma cortisol cannot therefore be used to confirm or refute the diagnosis, unless the value is above 500 nmol/L (\(>18 \mu g/dL\)), which effectively excludes adrenal insufficiency.

More useful is the short ACTH stimulation test (also called the tetracosactrin or short Synacthen test) described in Box 18.43. Cortisol levels fail to increase in response to exogenous ACTH in patients with primary or secondary adrenal insufficiency. These can be distinguished by measurement of ACTH (which is low in ACTH deficiency and high in Addison’s disease).

Assessment of mineralocorticoids

Mineralocorticoid secretion in patients with suspected Addison’s disease cannot be adequately assessed by electrolyte measurements since hyponatraemia occurs in both aldosterone and cortisol deficiency (see Box 18.42 and p. 357). Hyperkalaemia is common, but not universal, in aldosterone deficiency. Plasma renin and aldosterone should be measured in the supine position. In mineralocorticoid deficiency, plasma renin activity is high, with plasma aldosterone being either low or in the lower part of the reference range.

Assessment of adrenal androgens

This is not necessary in men because testosterone from the testes is the principal androgen. In women, dehydroepiandrosterone sulphate (DHEAS) and androstenedione may be measured in a random specimen of blood, though levels are highest in the morning.

Investigations

Treatment should not be delayed to wait for results in patients with suspected acute adrenal crisis. Here, a random blood sample should be stored for subsequent measurement of serum cortisol and, if possible, plasma ACTH; if the patient’s clinical condition permits, it may be appropriate to spend 30 minutes performing a short ACTH stimulation test (Box 18.43) before administering hydrocortisone, but delays must be avoided if there is circulatory compromise. Investigations should be performed before treatment is given in patients who present with features suggestive of chronic adrenal insufficiency.
the cause of Addison’s disease. Adrenal autoantibodies are frequently positive in autoimmune adrenal failure. If antibody tests are negative, imaging of the adrenal glands with CT or MRI is indicated. Tuberculosis causes adrenal calcification, visible on plain X-ray or ultrasound scan. A human immunodeficiency virus (HIV) test should be performed if risk factors for infection are present (p. 310). Adrenal metastases are a rare cause of adrenal insufficiency. Patients with evidence of autoimmune adrenal failure should be screened for other organ-specific autoimmune diseases, such as thyroid disease, pernicious anaemia and type 1 diabetes.

Management

Patients with adrenocortical insufficiency always need glucocorticoid replacement therapy and usually, but not always, mineralocorticoid therapy. There is some evidence that adrenal androgen replacement may also be beneficial in women. Other treatments depend on the underlying cause. The emergency management of adrenal crisis is described in Box 18.44.

Glucocorticoid replacement

Adrenal replacement therapy consists of oral hydrocortisone (cortisol) 15–20 mg daily in divided doses, typically 10 mg on waking and 5 mg at around 1500 hrs. These are physiological replacement doses that should not cause Cushingoid side-effects. The dose may need to be adjusted for the individual patient but this is subjective. Excess weight gain usually indicates over-replacement, while persistent lethargy or hyperpigmentation may be due to an inadequate dose or lack of absorption. Measurement of serum cortisol levels is not usually helpful. Advice to patients dependent on glucocorticoid replacement is given in Box 18.40.

Mineralocorticoid replacement

Fludrocortisone (α-fluoro-hydrocortisone) is administered at the usual dose of 0.05–0.15 mg daily, and adequacy of replacement may be assessed by measurement of blood pressure, plasma electrolytes and plasma renin. It is indicated for virtually every organ system in an attempt to normalise fluid balance and plasma volume. Dosages are usually given in Box 18.40.

18.45 Glucocorticoids in old age

- **Adrenocortical insufficiency**: often insidious and may present with tiredness, drowsiness, delirium, falls, immobility and orthostatic hypotension.
- **Glucocorticoid therapy**: especially hazardous in older people, who are already relatively immunocompromised and susceptible to osteoporosis, diabetes, hypertension and other complications.
- “Physiological” glucocorticoid replacement therapy: increased risk of adrenal crisis because adherence may be poor and there is a greater incidence of intercurrent illness. Patient and carer education, with regular reinforcement of the principles described in Box 18.40, is crucial.

Androgen replacement

Androgen replacement with DHEAS (50 mg/day) is occasionally given to women with primary adrenal insufficiency who have symptoms of reduced libido and fatigue, but the evidence in support of this is not robust and treatment may be associated with side-effects such as acne and hirsutism.

Incidental adrenal mass

It is not uncommon for a mass in the adrenal gland to be identified on a CT or MRI scan of the abdomen that has been performed for another indication. Such lesions are known as adrenal ‘incidentalomas’. The prevalence increases with age and they are present in up to 10% of adults aged 70 years and older. Eighty-five per cent of adrenal incidentalomas are non-functioning adenomas. The remainder includes functional tumours of the adrenal cortex (secreting cortisol, aldosterone or androgens), pheochromocytomas, primary and secondary carcinomas, hamartomas and other rare disorders, including granulomatous infiltrations.

Clinical assessment and investigations

There are two key questions to be resolved: is the lesion secreting hormones, and is it benign or malignant?

Patients with an adrenal incidentaloma are usually asymptomatic. However, clinical signs and symptoms of excess glucocorticoids (p. 665), mineralocorticoids (see below), catecholamines (p. 666) and, in women, androgens (p. 666) should be sought. Investigations should include a doxamethasone suppression test, urine or plasma metanephrines and, in virilised women, measurement of serum testosterone, DHEAS and androstenedione. Patients with hypertension should be investigated for mineralocorticoid excess, as described below. In bilateral masses consistent with adrenocortical lesions, 17-OH-progesterone should also be measured.

CT and MRI are equally effective in assessing the malignant potential of an adrenal mass, using the following parameters:

- **Size**. The larger the lesion, the greater the malignant potential. Around 90% of adrenocortical carcinomas are over 4 cm in diameter, but specificity is poor since only approximately 25% of such lesions are malignant.
- **Configuration**. Homogeneous and smooth lesions are more likely to be benign. The presence of metastatic lesions elsewhere increases the risk of malignancy, but as many as two-thirds of adrenal incidentalomas in patients with cancer are benign.
- **Presence of lipid**. Adenomas are usually lipid-rich, resulting in an attenuation of below 10 Hounsfield units (HU) on
an unenhanced CT, and in signal dropout on chemical shift MRI.

- *Enhancement*. Benign lesions demonstrate rapid washout of contrast, whereas malignant lesions tend to retain contrast.

Histology in a sample obtained by CT-guided biopsy is rarely indicated, and is not useful in distinguishing an adrenal adenoma from an adrenocortical carcinoma. Biopsy is occasionally helpful in confirming adrenal metastases from other cancers, but should be avoided if either phaeochromocytoma or primary adrenal cancer is suspected in order to avoid precipitation of a hypertensive crisis or seeding of tumour cells, respectively.

### Management

In patients with radiologically benign, non-functioning lesions of less than 4 cm in diameter, surgery is required only if serial imaging suggests tumour growth. Functional lesions and tumours of more than 4 cm in diameter should be considered for surgery, though many centres will not operate on tumours of more than 4 cm if all other characteristics suggest benign disease. Optimal management of patients with low-grade cortisol secretion, as demonstrated by the dexamethasone suppression test, remains to be established.

#### Primary hyperaldosteronism

Estimates of the prevalence of primary hyperaldosteronism vary according to the screening tests employed, but it may occur in as many as 10% of people with hypertension. Indications to test for mineralocorticoid excess in hypertensive patients include hypokalaemia (including hypokalaemia induced by thiazide diuretics), poor control of blood pressure with conventional therapy, a family history of early-onset hypertension, or therapy, a family history of early-onset hypertension, or

- Inadequate renal perfusion (diuretic therapy, cardiac failure, liver failure, nephrotic syndrome, renal artery stenosis)
- Renin-secreting renal tumour (very rare)

(11β-HSD2 = 11β-hydroxysteroid dehydrogenase type 2; ACTH = adrenocorticotrophic hormone)

#### Clinical features

Individuals with primary hyperaldosteronism are usually asymptomatic but may have features of sodium retention or potassium loss. Sodium retention may cause oedema, while hypokalaemia may cause muscle weakness (or even paralysis, especially in South-east Asian populations), polyuria (secondary to renal tubular damage, which produces nephrogenic diabetes insipidus) and occasionally tetany (because of associated metabolic alkalosis and low ionised calcium). Blood pressure is elevated but accelerated phase hypertension is rare.

#### Investigations

**Biochemical**

Routine blood tests may show a hypokalaemic alkalosis. Sodium is usually at the upper end of the reference range in primary hyperaldosteronism, but is characteristically low in secondary hyperaldosteronism (because low plasma volume stimulates vasopressin (antidiuretic hormone, ADH) release and high angiotensin II levels stimulate thirst). The key measurements are plasma renin and aldosterone (Box 18.46), and in many centres the aldosterone : renin ratio (ARR) is employed as a screening test for primary hyperaldosteronism in hypertensive patients. Almost all antihypertensive drugs interfere with this ratio (β-blockers inhibit while diuretics stimulate renin secretion). Thus, individuals with an elevated ARR require further testing after stopping antihypertensive drugs for at least 4 weeks. If necessary, antihypertensive agents that have minimal effects on the renin–angiotensin system, such as calcium antagonists and α-blockers, may be substituted. Oral potassium supplementation may also be required, as hypokalaemia itself suppresses renin activity. If, on repeat testing, plasma renin is low and aldosterone concentrations are elevated, then further investigation under specialist supervision may include suppression tests (sodium loading) and/or stimulation tests (captopril or furosemide administration) to differentiate angiotensin II-dependent aldosterone secretion in idiopathic hyperplasia from autonomous aldosterone secretion typical of an APA.

**Imaging and localisation**

Imaging with CT or MRI will identify most APAs (Fig. 18.23) but it is important to recognise the risk of false positives (non-functioning adrenal adenomas are common) and false negatives (imaging may have insufficient resolution to identify adenomas with a diameter of less than 0.5 cm). If the imaging is inconclusive and there is an intention to proceed with surgery on the basis of strong biochemical evidence of an APA, then adrenal vein catheterisation with measurement of aldosterone (and cortisol to confirm positioning of the catheters) is required. In some centres, this is performed even in the presence of a unilateral ‘adenoma’, to avoid inadvertent removal of an incidental non-functioning adenoma contralateral to a radiologically apparent cause of aldosterone excess.
dehydrogenase B, C and D genes. Other genetic causes include mutations in SDHA, SDHAF2, TMEN127 and MAX.

**Clinical features**

These depend on the pattern of catecholamine secretion and are listed in Box 18.47.

Some patients present with hypertension, although it has been estimated that phaeochromocytoma accounts for less than 0.1% of cases of hypertension. The presentation may be with a complication of hypertension, such as stroke, myocardial infarction, left ventricular failure, hypertensive retinopathy or accelerated phase hypertension. The apparent paradox of postural hypotension between episodes is explained by ‘pressure natriuresis’ during hypertensive episodes so that intravascular volume is reduced. There may also be features of the familial syndromes associated with phaeochromocytoma. Paragangliomas are often non-functioning.

**Investigations**

Excessive secretion of catecholamines can be confirmed by measuring metabolites in plasma and/or urine (metanephrine and normetanephrine). There is a high 'false-positive' rate, as misleading metanephrine concentrations may be seen in stressed patients (during acute illness, following vigorous exercise or severe pain) and following ingestion of some drugs such as tricyclic antidepressants. For this reason, a repeat sample should usually be requested if elevated levels are found, although, as a rule, the higher the concentration of metanephrines, the more likely the diagnosis of phaeochromocytoma/paraganglioma.

Serum chromogranin A is often elevated and may be a useful tumour marker in patients with non-secretory tumours and/or metastatic disease. Genetic testing should be considered in individuals with other features of a genetic syndrome, in those with a family history of phaeochromocytoma/paraganglioma, and in those presenting under the age of 50 years.

**Localisation**

Phaeochromocytomas are usually identified by abdominal CT or MRI (Fig. 18.24). Localisation of paragangliomas may be more difficult. Scintigraphy using meta-iodobenzyl guanidine (MIBG) can be useful, particularly if combined with CT, for adrenal phaeochromocytoma but is often negative in paraganglioma. 

**Management**

In functioning tumours, medical therapy is required to prepare the patient for surgery, preferably for a minimum of 6 weeks,
Congenital adrenal hyperplasia

Pathophysiology and clinical features

Inherited defects in enzymes of the cortisol biosynthetic pathway (see Fig. 18.19) result in insufficiency of hormones downstream of the block, with impaired negative feedback and increased ACTH secretion. ACTH then stimulates the production of steroids upstream of the enzyme block. This produces adrenal hyperplasia and a combination of clinical features that depend on the severity and site of the defect in biosynthesis. All of these enzyme abnormalities are inherited as autosomal recessive traits.

The most common enzyme defect is 21-hydroxylase deficiency. This results in impaired synthesis of cortisol and aldosterone, and accumulation of 17-OH-progesterone, which is then diverted to form adrenal androgens. In about one-third of cases, this defect is severe and presents in infancy with features of glucocorticoid and mineralocorticoid deficiency (see Box 18.42) and androgen excess, such as ambiguous genitalia in girls. In the other two-thirds, mineralocorticoid secretion is adequate but there may be features of cortisol insufficiency and/or ACTH and androgen excess, including precocious pseudo-puberty, which is distinguished from ‘true’ precocious puberty by low gonadotrophins. Sometimes the mildest enzyme defects are not apparent until adult life, when females may present with amenorrhea and/or hirsutism (pp. 762 and 763). This is called ‘non-classical’ or ‘late-onset’ congenital adrenal hyperplasia.

Defects of all the other enzymes in Figure 18.19 are rare. Both 17-hydroxylase and 11β-hydroxylase deficiency may produce hypertension due to excess production of 11-deoxycorticosterone, which has mineralocorticoid activity.

Investigations

Circulating 17-OH-progesterone levels are raised in 21-hydroxylase deficiency but this may be demonstrated only after ACTH administration in late-onset cases. To avoid salt-wasting crises in infancy, 17-OH-progesterone can be routinely measured in heelpick blood spot samples taken from all infants in the first week of life. Assessment is otherwise as described for adrenal insufficiency on page 672.

In siblings of affected children, antenatal genetic diagnosis can be made by amniocentesis or chorionic villus sampling. This allows prevention of virilisation of affected female fetuses by administration of dexamethasone to the mother to suppress ACTH levels.

Management

The aim is to replace deficient corticosteroids and to suppress ACTH-driven adrenal androgen production. A careful balance is required between adequate suppression of adrenal androgen excess and excessive glucocorticoid replacement resulting in features of Cushing’s syndrome. In children, growth velocity is an important measurement, since either under- or over-replacement with glucocorticoids suppresses growth. In adults, there is no uniformly agreed adrenal replacement regime, and clinical features (menstrual cycle, hirsutism, weight gain, blood pressure) and biochemical profiles (plasma renin, 17-OH-progesterone and testosterone levels) provide a guide.

Women with late-onset 21-hydroxylase deficiency may not require corticosteroid replacement. If hirsutism is the main problem, anti-androgen therapy may be just as effective (p. 659).

The endocrine pancreas and gastrointestinal tract

A series of hormones are secreted from cells distributed throughout the gastrointestinal tract and pancreas. Functional anatomy and physiology are described on pages 723 and 848. Diseases associated with abnormalities of these hormones are listed in Box 18.48. Most are rare, with the exception of diabetes mellitus (Ch. 20).

Presenting problems in endocrine pancreas disease

Spontaneous hypoglycaemia

Hypoglycaemia most commonly occurs as a side-effect of treatment with insulin or sulphonylurea drugs in people with
diabetes mellitus. In non-diabetic individuals, symptomatic hypoglycaemia is rare, but it is not uncommon to detect venous blood glucose concentrations below 3.0 mmol/L (54 mg/dL) in asymptomatic patients. For this reason, and because the symptoms of hypoglycaemia are non-specific, a hypoglycaemic disorder should be diagnosed only if all three conditions of Whipple’s triad are met (Fig. 18.25). There is no specific blood concentration at which spontaneous hypoglycaemia can be said to occur, although the lower the blood glucose concentration, the more likely it is to have pathological significance. Investigations are unlikely to be needed unless glucose concentrations below 3.0 mmol/L are observed, many patients with true hypoglycaemia demonstrating glucose levels below 2.2 mmol/L (40 mg/dL).

**Clinical assessment**

The clinical features of hypoglycaemia are described in the section on insulin-induced hypoglycaemia on page 738. Individuals with chronic spontaneous hypoglycaemia often have attenuated autonomic responses and ‘hypoglycaemia unawares’, and may present with a wide variety of features of neuroglycopenia, including odd behaviour and convulsions. The symptoms are usually episodic and relieved by consumption of carbohydrate. Symptoms occurring while fasting (such as before breakfast) or following exercise are much more likely to be representative of pathological hypoglycaemia than those that develop after food (post-prandial or ‘reactive’ symptoms). Hypoglycaemia should be considered in all comatose patients, even if there is an apparently obvious cause, such as hemiplegic stroke or alcohol intoxication.

**Investigations**

**Does the patient have a hypoglycaemic disorder?**

Patients who present acutely with delirium, coma or convulsions should be tested for hypoglycaemia at the bedside with a capillary blood sample and an automated meter. While this is sufficient to exclude hypoglycaemia, blood glucose meters are relatively inaccurate in the hypoglycaemic range and the diagnosis should always be confirmed by a laboratory-based glucose measurement. At the same time, a sample should be taken for later measurement of alcohol, insulin, C-peptide, cortisol and sulphonylurea levels, if hypoglycaemia is confirmed. Taking these samples during an acute presentation prevents subsequent unnecessary dynamic tests and is of medico-legal importance in cases where poisoning is suspected.

Patients who attend the outpatient clinic with episodic symptoms suggestive of hypoglycaemia present a more challenging problem. The main diagnostic test is the prolonged (72-hour) fast. If symptoms of hypoglycaemia develop during the fast, then blood samples should be taken to confirm hypoglycaemia and for later measurement of insulin and C-peptide. Hypoglycaemia is then corrected with oral or intravenous glucose and Whipple’s triad completed by confirmation of the resolution of symptoms. The absence of clinical and biochemical evidence of hypoglycaemia during a prolonged fast effectively excludes the diagnosis of a hypoglycaemic disorder.

**What is the cause of the hypoglycaemia?**

In the acute setting, the underlying diagnosis is often obvious. In non-diabetic individuals, alcohol excess is the most common cause of hypoglycaemia in the UK but other drugs – e.g. salicylates, quinine and pentamidine – may also be implicated. Hypoglycaemia is one of many metabolic derangements that occur in patients with hepatic failure, renal failure, adrenal insufficiency, sepsis or malaria.

Hypoglycaemia in the absence of insulin, or any insulin-like factor, in the blood indicates impaired gluconeogenesis and/or availability of glucose from glycogen in the liver. Hypoglycaemia associated with high insulin and low C-peptide concentrations is indicative of administration of exogenous insulin, either factitiously or feloniously. Adults with high insulin and C-peptide concentrations during an episode of hypoglycaemia are most likely to have an insulinoma but sulphonylurea ingestion should also be considered (particularly in individuals with access to such medication, such as health-care professionals or family members of someone with type 2 diabetes). Suppressed plasma β-hydroxybutyrate helps confirm inappropriate insulin secretion during fasting. Usually, insulinomas in the pancreas

are small (<5 mm diameter) but can be identified by CT, MRI or ultrasound (endoscopic or laparoscopic). Imaging should include the liver since around 10% of insulinomas are malignant and may metastasise to the liver. Rarely, large non-pancreatic tumours, such as sarcomas, may cause recurrent hypoglycaemia because of their ability to produce excess pro-insulin-like growth factor-2 (pro-IGF-2), which has considerable structural homology to insulin.

Management

Treatment of acute hypoglycaemia should be initiated as soon as laboratory blood samples have been taken and should not be deferred until formal laboratory confirmation has been obtained. Intravenous dextrose (5% or 10%) is effective in the short term in the obtunded patient and should be followed on recovery with oral unrefined carbohydrate (starch). Continuous dextrose infusion may be necessary, especially in sulphonylurea poisoning. Intramuscular glucagon (1 mg) stimulates hepatic glucose release but is ineffective in patients with depleted glycogen reserves, such as in alcohol excess or liver disease.

Chronic recurrent hypoglycaemia in insulin-secreting tumours can be treated by regular consumption of oral carbohydrate combined with agents that inhibit insulin secretion (diazoxide or somatostatin analogues). Insulinomas are resected when benign, providing the individual is fit enough to undergo surgery. Metastatic malignant insulinomas may be incurable and are managed along the same lines as other metastatic neuro-endocrine tumours (see below).

Gastroenteropancreatic neuro-endocrine tumours

Neuro-endocrine tumours (NETs) are a heterogeneous group derived from neuro-endocrine cells in many organs, including the gastrointestinal tract, lung, adrenals (phaeochromocytoma, p. 675) and thyroid (medullary carcinoma, p. 650). Most NETs occur sporadically but a proportion are associated with genetic cancer syndromes, such as MEN 1, 2 and 3 and neurofibromatosis type 1 (pp. 688 and 1131). NETs may secrete hormones into the circulation.

Gastroenteropancreatic NETs arise in organs that are derived embryologically from the gastrointestinal tract. Most commonly, they occur in the small bowel but they can also arise elsewhere in the bowel, pancreas, thymus and bronchi. The term ‘carcinoid’ is often used when referring to non-pancreatic gastroenteropancreatic NETs because, when initially described, they were thought to behave in an indolent fashion compared with conventional cancers. It is now recognised that there is a wide spectrum of malignant potential for all NETs; some are benign (most insulinomas and appendiceal carcinoid tumours), while others have an aggressive clinical course with widespread metastases (small-cell carcinoma of the lung). The majority of gastroenteropancreatic NETs behave in an intermediate manner, with relatively slow growth but a propensity to invade and metastasise to remote organs, especially the liver.

Clinical features

Patients with gastroenteropancreatic NETs often have a history of abdominal pain over many years prior to diagnosis and usually present with local mass effects, such as small-bowel obstruction, appendicitis, and pain from hepatic metastases. Thyroid and bronchial carcinoids occasionally present with ectopic ACTH syndrome (p. 667). Pancreatic NETs can also cause hormone excess (Box 18.50) but most are non-functional. The classic ‘carcinoid syndrome’ (Box 18.51) occurs when vasoactive hormones reach the systemic circulation. In the case of gastrointestinal carcinoids, this invariably means that the tumour has metastasised to the liver or there are peritoneal deposits, which allow secreted hormones to gain access to the systemic circulation; hormones secreted by the primary tumour into the portal vein are metabolised and inactivated in the liver. The features of Zollinger–Ellison syndrome are described on page 802.

Investigations

A combination of imaging with ultrasound, CT, MRI and/or radio-labelled somatostatin analogue (Fig. 18.26) will usually identify the primary tumour and allow staging, which is crucial for determining prognosis. Biopsy of the primary tumour or a metastatic deposit is required to confirm the histological type. NETs demonstrate immunohistochemical staining for the proteins chromogranin A and synaptophysin, and the histological grade provides important prognostic information: the higher the Ki67 proliferation index, the worse the prognosis.

Carcinoid syndrome is confirmed by measuring elevated concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, in a 24-hour urine collection. False positives can occur, particularly if the individual has been eating certain foods, such as avocado and pineapple. Plasma chromogranin A can be measured in a fasting blood sample, along with the hormones listed in Box 18.50. All of these can be useful as tumour markers.
The hypothalamus and the pituitary gland

Diseases of the hypothalamus and pituitary have an annual incidence of approximately 3:100,000 and a prevalence of 30–70 per 100,000. The pituitary plays a central role in several major endocrine axes, so that investigation and treatment invariably involve several other endocrine glands.

Management

Treatment of solitary tumours is by surgical resection. If metastatic or multifocal primary disease is present, then surgery is usually not indicated, unless there is a complication such as gastrointestinal obstruction. Diazoxide can reduce insulin secretion in insulinomas, and high doses of proton pump inhibitors suppress acid production in gastrinomas. Somatostatin analogues are effective in reducing the symptoms of carcinoid syndrome and of excess glucagon and vasoactive intestinal peptide (VIP) production. The slow-growing nature of NETs means that conventional cancer therapies, such as chemotherapy and radiotherapy, have limited efficacy, but use of somatostatin analogues is associated with improved progression-free survival. Other treatments, such as interferon, targeted radionuclide therapy with $^{131}$I-MIBG and radio-labelled somatostatin analogues (which may be taken up by NET metastases), and resection/embolisation/ablation of hepatic metastases, may have a role in the palliation of symptoms but debate exists as to whether this prolongs life. The tyrosine kinase inhibitor sunitinib and the mammalian target of rapamycin (mTOR) inhibitor everolimus have shown significant improvements in progression-free survival in patients with advanced and progressive pancreatic and lung NETS that are not poorly differentiated, and should be considered as part of standard therapy.

The hypothalamus and the pituitary gland

The anatomical relationships of the pituitary are shown in Figure 18.27 and its numerous functions are shown in Figure 18.2 (p. 633). The pituitary gland is enclosed in the sella turcica and bridged over by a fold of dura mater called the diaphragma sellae, with the sphenoidal air sinuses below and the optic chiasm above. The cavernous sinuses are lateral to the pituitary fossa and contain the 3rd, 4th and 6th cranial nerves and the internal carotid arteries. The gland is composed of two lobes, anterior and posterior, and is connected to the hypothalamus by the infundibular stalk, which has portal vessels carrying blood from the median eminence of the hypothalamus to the anterior lobe and nerve fibres to the posterior lobe.
Diseases of the hypothalamus and pituitary are classified in Box 18.52. By far the most common disorder is an adenoma of the anterior pituitary gland.

**Investigation of patients with pituitary disease**

Although pituitary disease presents with diverse clinical manifestations (see below), the approach to investigation is similar in all cases (Box 18.53).

The approach to testing for hormone deficiency is outlined in Box 18.53. Details are given in the sections on individual glands elsewhere in this chapter. Tests for hormone excess vary according to the hormone in question. For example, prolactin is not secreted in pulsatile fashion, although it rises with significant psychological stress. Assuming that the patient was not distressed by venepuncture, a random measurement of serum prolactin is sufficient to diagnose hyperprolactinaemia. In contrast, growth hormone is secreted in a pulsatile fashion. A high random level does not confirm acromegaly; the diagnosis is confirmed only by failure of growth hormone to be suppressed during an oral glucose tolerance test, and a high serum insulin-like growth factor-1 (IGF-1).

Similarly, in suspected ACTH-dependent Cushing’s disease (p. 666), random measurement of plasma cortisol is unreliable and the diagnosis is usually made by a dexamethasone suppression test.

The most common local complication of a large pituitary tumour is compression of the optic pathway. The resulting visual field defect can be documented using a Goldman’s perimetry chart.

MRI reveals ‘abnormalities’ of the pituitary gland in as many as 10% of ‘healthy’ middle-aged people. It should therefore be performed only if there is a clear biochemical abnormality or if a patient presents with clinical features of pituitary tumour (see below).

A pituitary tumour may be classified as either a macroadenoma (>10 mm diameter) or a microadenoma (<10 mm diameter).

Surgical biopsy is usually only performed as part of a therapeutic operation. Conventional histology identifies tumours as chromophobe (usually non-functioning), acidophil (typically prolactin- or growth hormone-secreting) or basophil (typically ACTH-secreting); immunohistochemistry may confirm their secretory capacity but is poorly predictive of growth potential of the tumour.

### 18.53 How to investigate patients with suspected pituitary hypothalamic disease

**Identify pituitary hormone deficiency**

- **ACTH deficiency**
  - Short ACTH stimulation test (see Box 18.43)
  - Insulin tolerance test (see Box 18.56): only if there is uncertainty in interpretation of short ACTH stimulation test (e.g. acute presentation)

- **LH/FSH deficiency**
  - In the male, measure random serum testosterone, LH and FSH
  - In the pre-menopausal female, ask if the menses are regular
  - In the post-menopausal female, measure random serum LH and FSH (FSH normally > 30 IU/L and LH > 20 IU/L)

- **TSH deficiency**
  - Measure random serum T4
  - Note that TSH is often detectable in secondary hypothyroidism

- **Growth hormone deficiency**
  - Only investigate if growth hormone replacement therapy is being contemplated (p. 682)
  - Measure immediately after exercise
  - Consider other stimulatory tests (see Box 18.55)

- **Cranial diabetes insipidus**
  - Only investigate if patient complains of polyuria/polydipsia, which may be masked by ACTH or TSH deficiency
  - Exclude other causes of polyuria with blood glucose, potassium and calcium measurements
  - Water deprivation test (see Box 18.61) or 5% saline infusion test

**Identify hormone excess**

- Measure random serum prolactin
- Investigate for acromegaly (glucose tolerance test) or Cushing’s syndrome (p. 667) if there are clinical features

**Establish the anatomy and diagnosis**

- Consider visual field testing
- Image the pituitary and hypothalamus by MRI or CT

(ACTH = adrenocorticotropic hormone; FSH = follicle-stimulating hormone; LH = luteinising hormone; TSH = thyroid-stimulating hormone)
The hypothalamus and the pituitary gland

Presenting problems in hypothalamic and pituitary disease

The clinical features of pituitary disease are shown in Figure 18.28. Younger women with pituitary disease most commonly present with secondary amenorrhea (p. 654) or galactorrhoea (in hyperprolactinaemia). Post-menopausal women and men of any age are less likely to report symptoms of hypogonadism and so are more likely to present late with larger tumours causing visual field defects. Nowadays, many patients present with the incidental finding of a pituitary tumour on a CT or MRI scan.

Hypopituitarism

Hypopituitarism describes combined deficiency of any of the anterior pituitary hormones. The clinical presentation is variable and depends on the underlying lesion and the pattern of resulting hormone deficiency. The most common cause is a pituitary macroadenoma but other causes are listed in Box 18.54.

Clinical assessment

The presentation is highly variable. For example, following radiotherapy to the pituitary region, there is a characteristic sequence of loss of pituitary hormone secretion. Growth hormone secretion is often the earliest to be lost. In adults, this produces lethargy, muscle weakness and increased fat mass but these features are not obvious in isolation. Next, gonadotrophin (LH and FSH) secretion becomes impaired with loss of libido in the male and oligomenorrhea or amenorrhea in the female. Later, in the male there may be gynaecomastia and decreased frequency of shaving. In both sexes, axillary and pubic hair eventually become

Hormone excess

Hyperprolactinaemia
  • Galactorrhoea
  • Amenorrhoea
  • Hypogonadism

Acromegaly
  • Headache
  • Sweating
  • Change in shoe and ring size

  • Weight gain
  • Bruising
  • Myopathy
  • Hypertension
  • Striae
  • Depression

Hypopituitarism

• Growth hormone
  • Lethargy

Gonadotrophins
  • Lethargy
  • Loss of libido
  • Hair loss
  • Amenorrhoea

ACTH
  • Lethargy
  • Postural hypotension
  • Pallor
  • Hair loss

TSH
  • Lethargy

Vasopressin
  (usually post-surgical)
  • Thirst and polyuria

Local complications

• Headache
• Visual field defect
• Disconnection hyperprolactinaemia
• Diplopia (cavernous sinus involvement)
• Acute infarction/expansion (pituitary apoplexy)

18.54 Causes of anterior pituitary hormone deficiency

Structural
• Primary pituitary tumour
• Adenoma*
• Carcinoma (exceptionally rare)
• Cranialpharyngioma*
• Meningioma*
• Secondary tumour (including leukaemia and lymphoma)
• Chordoma
• Germinoma (pinealoma)
• Arachnoid cyst
• Rathke’s cleft cyst
• Haemorrhage (apoplexy)

Inflammatory/infiltrative
• Sarcoidosis
• Infections, e.g. pituitary abscess, tuberculosis, syphilis, encephalitis
• Lymphocytic hypophysitis
• Haemochromatosis
• Langerhans cell histiocytosis

Congenital deficiencies
• GnRH (Kallmann’s syndrome)*
• GHRH*
• TRH
• CRH

Functional*
• Chronic systemic illness
• Anorexia nervosa
• Excessive exercise

Other
• Head injury*
• (Para)sellar surgery*
• (Para)sellar radiotherapy*
• Post-partum necrosis (Sheehan’s syndrome)
• Opiate analgesia

*The most common causes of pituitary hormone deficiency.

CRH = corticotrophin-releasing hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; TRH = thyrotrophin-releasing hormone

Fig. 18.28 Common symptoms and signs to consider in a patient with suspected pituitary disease. (ACTH = adrenocorticotropic hormone; TSH = thyroid-stimulating hormone)
spare or even absent and the skin becomes characteristically finer and wrinkled. Chronic anaemia may also occur. The next hormone to be lost is usually ACTH, resulting in symptoms of cortisol insufficiency (including postural hypotension and a dilutional hyponatraemia). In contrast to primary adrenal insufficiency (p. 671), angiotensin II-dependent zona glomerulosa function is not lost and hence aldosterone secretion maintains normal plasma potassium. In contrast to the pigmentation of Addison’s disease due to high levels of circulating ACTH acting on the skin melanocytes, a striking degree of pallor is usually present. Finally, TSH secretion is lost with consequent secondary hypothyroidism. This contributes further to apathy and cold intolerance. In contrast to primary hypothyroidism, frank myxoedema is rare, presumably because the thyroid retains some autonomous function. The onset of all of the above symptoms is notoriously insidious. However, patients sometimes present acutely unwell with glucocorticoid deficiency. This may be precipitated by a mild infection or injury, or may occur secondary to pituitary apoplexy (p. 683).

Other features of pituitary disease may be present (Fig. 18.28).

Investigations
The strategy for investigation of pituitary disease is described in Box 18.53. In acutely unwell patients, the priority is to diagnose and treat cortisol deficiency (p. 672). Other tests can be undertaken later. Specific dynamic tests for diagnosing hormone deficiency are described in Boxes 18.43 and 18.55. More specialised biochemical tests, such as insulin tolerance tests (Box 18.56), GnRH and TRH tests, are rarely required. All patients with biochemical evidence of pituitary hormone deficiency should have an MRI or CT scan to identify pituitary or hypothalamic tumours. If a tumour is not identified, then further investigations are indicated to exclude infectious or infiltrative causes.

Management
Treatment of acutely ill patients is similar to that described for adrenocortical insufficiency on page 673, except that sodium depletion is not an important component to correct. Chronic hormone replacement therapies are described below. Once the cause of hypopituitarism is established, specific treatment – of a pituitary macroadenoma, for example (see below) – may be required.

Cortisol replacement
Hydrocortisone should be given if there is ACTH deficiency. Suitable doses are described in the section on adrenal disease on page 672. Mineralocorticoid replacement is not required.

Thyroid hormone replacement
Levothyroxine 50–150 μg once daily should be given as described on page 640. Unlike in primary hypothyroidism, measuring

<table>

</tr>
</thead>
</table>
GH levels are commonly undetectable, so a choice from the range of ‘stimulation’ tests is required:
- Insulin-induced hypoglycaemia
- Arginine (may be combined with GHRH)
- Glucagon
- Clonidine (in children)

(GH = growth hormone; GHRH = growth hormone-releasing hormone)

<table>
<thead>
<tr>
<th>18.56 How and when to do an insulin tolerance test</th>
</tr>
</thead>
</table>
Use
- Assessment of the HPA axis
- Assessment of GH deficiency
- Indicated when there is doubt after the other tests in Box 18.53
- Usually performed in specialist centres, especially in children
- IV glucose and hydrocortisone must be available for resuscitation

Contraindications
- Ischaemic heart disease
- Epilepsy
- Severe hypopituitarism (0800 hrs plasma cortisol <180 nmol/L (6.6 μg/dL))

Dose
- 0.15 U/kg body weight soluble insulin IV

Aim
- To produce adequate hypoglycaemia (tachycardia and sweating with blood glucose <2.2 mmol/L (40 mg/dL))

Blood samples
- 0, 30, 45, 60, 90, 120 mins for blood glucose, plasma cortisol and growth hormone

Results
- Normal subjects: GH > 6.7 μU/L (20 mIU/L)*
- Normal subjects: cortisol >550 nmol/L (approximately 20.2 μg/dL)*

*The precise cut-off figure for a satisfactory cortisol and GH response depends on the assay used and so varies between centres.

TSH is not helpful in adjusting the replacement dose because patients with hypopituitarism often secrete glycoproteins that are measured in the TSH assays but are not bioactive. The aim is to maintain serum T4 in the upper part of the reference range. It is dangerous to give thyroid replacement in adrenal insufficiency without first giving glucocorticoid therapy, since this may precipitate adrenal crisis.

Sex hormone replacement
This is indicated if there is gonadotrophin deficiency in women under the age of 50 and in men to restore normal sexual function and to prevent osteoporosis (p. 1044).

Growth hormone replacement
Growth hormone (GH) is administered by daily subcutaneous self-injection to children and adolescents with GH deficiency and, until recently, was discontinued once the epiphyses had fused. However, although hypopituitary adults receiving ‘full’ replacement with hydrocortisone, levothyroxine and sex steroids are usually much improved by these therapies, some individuals remain lethargic and unwell compared with a healthy population. Some of these patients feel better, and have objective improvements in their fat: muscle mass ratio and other metabolic parameters, if they are also given GH replacement. Treatment with GH may also help young adults to achieve a higher peak bone mineral density. The principal side-effect is sodium retention, manifest as peripheral oedema or carpal tunnel syndrome if given in excess. For this reason, GH replacement should be started at a low dose, with monitoring of the response by measurement of serum IGF-1.
Pituitary tumours produce a variety of mass effects, depending on their size and location, but also present as incidental findings on CT or MRI, or with hypopituitarism, as described above. A wide variety of disorders can present as mass lesions in or around the pituitary gland (see Box 18.54). Most intrasellar tumours are pituitary macroadenomas (most commonly non-functioning adenomas; see Fig. 18.28), whereas suprasellar masses may be craniopharyngiomas (see Fig. 18.31). The most common cause of a parasellar mass is a meningioma.

Clinical assessment

Clinical features are shown in Figure 18.28. A common but non-specific presentation is with headache, which may be the consequence of stretching of the diaphragma sellae. Although the classical abnormalities associated with compression of the optic chiasm are bitemporal hemianopia (see Fig. 18.29) or upper quadrantanopia, any type of visual field defect can result from suprasellar extension of a tumour because it may compress the optic nerve (unilateral loss of acuity or scotoma) or the optic tract (homonymous hemianopia). Optic atrophy may be apparent on ophthalmoscopy. Lateral extension of a sellar mass into the cavernous sinus with subsequent compression of the 3rd, 4th or 6th cranial nerve may cause diplopia and strabismus, but in anterior pituitary tumours this is an unusual presentation.

Occasionally, pituitary tumours infarct or there is bleeding into cystic lesions. This is termed ‘pituitary apoplexy’ and may result in sudden expansion with local compression symptoms and acute-onset hypopituitarism. Non-haemorrhagic infarction can also occur in a normal pituitary gland; predisposing factors include catastrophic obstetric haemorrhage (Sheehan’s syndrome), diabetes mellitus and raised intracranial pressure.

Investigations

Patients suspected of having a pituitary tumour should undergo MRI or CT. While some lesions have distinctive neuro-radiological features, the definitive diagnosis is made on histology after surgery. All patients with (para)sellar space-occupying lesions should have pituitary function assessed as described in Box 18.53.

Management

Modalities of treatment of common pituitary and hypothalamic tumours are shown in Box 18.57. Associated hypopituitarism should be treated as described above.

Urgent treatment is required if there is evidence of pressure on visual pathways. The chances of recovery of a visual field defect are proportional to the duration of symptoms, with full recovery unlikely if the defect has been present for longer than 4 months. In the presence of a sellar mass lesion, it is crucial that serum prolactin is measured before emergency surgery is performed. If the prolactin is over 5000 mIU/L [236 ng/mL], then the lesion is likely to be a macroprolactinoma and should respond to a dopamine agonist with shrinkage of the lesion, making surgery unnecessary (see Fig. 18.29).

Most operations on the pituitary are performed using the trans-sphenoidal approach via the nostrils, while transfrontal surgery via a craniotomy is reserved for suprasellar tumours and is much less frequently needed. It is uncommon to be able to resect lateral extensions into the cavernous sinuses, although with modern endoscopic techniques this is more feasible. All operations on the pituitary carry a risk of damaging normal endocrine function; this risk increases with the size of the primary lesion.

Pituitary function (see Box 18.53) should be retested 4–6 weeks following surgery, primarily to detect the development of any new hormone deficits. Rarely, the surgical treatment of a sellar lesion can result in recovery of hormone secretion that was deficient pre-operatively.

Following surgery, usually after 3–6 months, imaging should be repeated. If there is a significant residual mass and the histology confirms an anterior pituitary tumour, external radiotherapy may be given to reduce the risk of recurrence but the risk-benefit ratio needs careful individualised discussion. Radiotherapy is not useful in patients requiring urgent therapy because it takes many months or years to be effective and there is a risk of acute swelling of the mass. Fractionated radiotherapy carries a life-long risk of hypopituitarism (50–70% in the first 10 years) and annual pituitary function tests are obligatory. There is also concern that radiotherapy might impair cognitive function, cause vascular changes and even induce primary brain tumours, but these side-effects have not been quantified reliably and are likely

(ACTH = adrenocorticotropic hormone; GH = growth hormone)
to be rare. Stereotactic radiosurgery allows specific targeting of residual disease in a more focused fashion.

Non-functioning tumours should be followed up by repeated imaging at intervals that depend on the size of the lesion and on whether or not radiotherapy has been administered. For smaller lesions that are not causing mass effects, therapeutic surgery may not be indicated and the lesion may simply be monitored by serial neuroimaging without a clear-cut diagnosis having been established.

Hyperprolactinaemia/galactorrhoea

Hyperprolactinaemia is a common abnormality that usually presents with hypogonadism and/or galactorrhoea (lactation in the absence of breastfeeding). Since prolactin stimulates milk secretion but not breast development, galactorrhoea rarely occurs in men and only does so if gynaecomastia has been induced by hypogonadism (p. 655). The differential diagnosis of hyperprolactinaemia is shown in Box 18.58. Many drugs, especially dopamine antagonists, elevate prolactin concentrations. Pituitary tumours can cause hyperprolactinaemia by directly secreting prolactin (prolactinomas, see below), or by compressing the infundibular stalk and thus interrupting the tonic inhibitory effect of hypothalamic dopamine on prolactin secretion (‘disconnection’ hyperprolactinaemia).

Prolactin usually circulates as a free (monomeric) hormone in plasma but, in some individuals, prolactin becomes bound to an IgG antibody. This complex is known as macroprolactin. Levels above 5000 mIU/L (236 ng/mL) are highly suggestive of a macroprolactinoma. Levels of normal for many assays of serum prolactin is approximately 500 mIU/L (24 ng/mL). In non-pregnant and non-lactating patients with hyperprolactinaemia, levels above 5000 mIU/L (24–47 ng/mL) are likely to be due to stress or drugs, and a repeat measurement is indicated. Levels between 1000 and 5000 mIU/L (47–236 ng/mL) are likely to be induced by stress or drugs, and a repeat measurement is indicated. Levels above 5000 mIU/L (236 ng/mL) are highly suggestive of a macroprolactinoma. Levels above 5000 mIU/L (236 ng/mL) are highly suggestive of a macroprolactinoma.

Patients with prolactin excess should have tests of gonadal function (p. 651), and T₄ and TSH should be measured to exclude primary hypothyroidism causing TRH-induced prolactin excess. Unless the prolactin falls after withdrawal of relevant drug therapy, a serum prolactin consistently above the reference range is an indication for MRI or CT scan of the hypothalamus and pituitary. Patients with a macroadenoma also need tests for hypopituitarism (see Box 18.53).

Management

If possible, the underlying cause should be corrected (e.g. cessation of offending drugs and giving levothyroxine replacement in primary hypothyroidism). If dopamine antagonists are the cause, then dopamine agonist therapy is contraindicated; if gonadal dysfunction is the primary concern, sex steroid replacement therapy may be indicated. Troublesome physiological galactorrhoea can also be treated with dopamine agonists (see Box 18.59). Management of prolactinomas is described below.

Prolactinoma

Most prolactinomas in pre-menopausal women are microadenomas because the symptoms of prolactin excess usually result in early presentation. Prolactin-secreting cells of the anterior pituitary share a common lineage with GH-secreting cells, so occasionally prolactinomas can secrete excess GH and cause acromegaly. In prolactinomas there is a relationship between prolactin concentration and tumour size: the higher the level, the bigger the tumour. Some macroprolactinomas can elevate prolactin concentrations above 100 000 mIU/L.

The investigation of prolactinomas is the same as for other pituitary tumours (see above).

**Management**
As shown in Box 18.57, several therapeutic modalities can be employed in the management of prolactinomas.

**Medical**
Dopamine agonist drugs are first-line therapy for the majority of patients (Box 18.59). They usually reduce serum prolactin concentrations and cause significant tumour shrinkage after several months of therapy (Fig. 18.29), but visual field defects, if present, may improve within days of first administration. It is possible to withdraw dopamine agonist therapy without recurrence of hyperprolactinaemia after a few years of treatment in some patients with a microadenoma. Also, after the menopause, suppression of prolactin is required in microadenomas only if galactorrhoea is troublesome, since hypogonadism is then physiological and tumour growth unlikely. In patients with macroadenomas, drugs can be withdrawn only after curative surgery or radiotherapy and under close supervision.

Ergot-derived dopamine agonists (bromocriptine and cabergoline) can bind to 5-HT<sub>2B</sub> receptors in the heart and elsewhere and have been associated with fibrotic reactions, particularly tricuspid valve regurgitation, when used in high doses in patients with Parkinson’s disease. At the relatively low doses used in prolactinomas most data suggest that systematic screening for cardiac fibrosis is unnecessary, but if dopamine agonist therapy is prolonged, periodic screening by echocardiography or use of non-ergot agents (quinagolide) may be indicated.

**Surgery and radiotherapy**
Surgical decompression is usually necessary only when a macroprolactinoma has failed to shrink sufficiently with dopamine agonist therapy, and this may be because the tumour has a significant cystic component. Surgery may also be performed in patients who are intolerant of dopamine agonists. Microadenomas can be removed selectively by trans-sphenoidal surgery with a cure rate of about 80%, but recurrence is possible; the cure rate for surgery in macroadenomas is substantially lower.

External irradiation may be required for some macroadenomas to prevent regrowth if dopamine agonists are stopped.

**Pregnancy**
Hyperprolactinaemia often presents with infertility, so dopamine agonist therapy may be followed by pregnancy. Patients with microadenomas should be advised to withdraw dopamine agonist therapy as soon as pregnancy is confirmed. In contrast, macroprolactinomas may enlarge rapidly under oestrogen stimulation and these patients should continue dopamine agonist therapy and need measurement of prolactin levels and visual fields during pregnancy. All patients should be advised to report headache or visual disturbance promptly.

**Acromegaly**
Acromegaly is caused by growth hormone (GH) secretion from a pituitary tumour, usually a macroadenoma, and carries an approximate twofold excess mortality when untreated.

* Tolerance develops for the side-effects. All of these agents, especially bromocriptine, must be introduced at low dose and increased slowly. If several doses of bromocriptine are missed, the process must start again.
Surgical Trans-sphenoidal surgery is usually the first line of treatment and may result in cure of GH excess, especially in patients with microadenomas. More often, surgery serves to debulk the tumour and further second-line therapy is required, according to post-operative imaging and glucose tolerance test results.

Radiotherapy External radiotherapy is usually employed as second-line treatment if acromegaly persists after surgery, to stop tumour growth and lower GH levels. However, GH levels fall slowly (over many years) and there is a risk of hypopituitarism.

Medical If acromegaly persists after surgery, medical therapy is usually employed to lower GH levels to below 1.0 μg/L (approximately 3 mIU/L) and to normalise IGF-1 concentrations. Medical therapy may be discontinued after several years in patients who have received radiotherapy. Somatostatin analogues (such as octreotide, lanreotide or pasireotide) can be administered as slow-release injections every few weeks. Somatostatin analogues can also be used as primary therapy for acromegaly either as an alternative or in advance of surgery, given evidence that they can induce modest tumour shrinkage in some patients. Dopamine agonists are less effective at lowering GH but may sometimes be helpful, especially with associated prolactin excess.

Clinical features If GH hypersecretion occurs before puberty, then the presentation is with gigantism. More commonly, GH excess occurs in adult life and presents with acromegaly. If hypersecretion starts in adolescence and persists into adult life, then the two conditions may be combined. The clinical features are shown in Figure 18.30. The most common complaints are headache and sweating. Additional features include those of any pituitary tumour (see Fig. 18.28).

Investigations The clinical diagnosis must be confirmed by measuring GH levels during an oral glucose tolerance test and measuring serum IGF-1. In normal subjects, plasma GH suppresses to below 0.5 μg/L (approximately 2 mIU/L). In acromegaly, GH does not suppress and in about 30% of patients there is a paradoxical rise; IGF-1 is also elevated. The rest of pituitary function should be investigated as described in Box 18.53. Prolactin concentrations are elevated in about 30% of patients due to co-secretion of prolactin from the tumour. Additional tests in acromegaly may include screening for colonic neoplasms with colonoscopy.

Management The main aims are to improve symptoms and to normalise serum GH and IGF-1 to reduce morbidity and mortality. Treatment is summarised in Box 18.57.
Pegvisomant is a peptide GH receptor antagonist administered by daily self-injection and may be indicated in some patients whose GH and IGF-1 concentrations fail to suppress sufficiently following somatostatin analogue therapy.

**Craniopharyngioma**

Craniopharyngiomas are benign tumours that develop in cell rests of Rathke’s pouch, and may be located within the sella turcica, or commonly in the suprasellar space. They are often cystic, with a solid component that may or may not be calcified (Fig. 18.31). In young people, they are diagnosed more commonly than pituitary adenomas. They may present with pressure effects on adjacent structures, hypopituitarism and/or cranial diabetes insipidus. Other clinical features directly related to hypothalamic damage may also occur. These include hyperphagia and obesity, loss of the sensation of thirst and disturbance of temperature regulation, and these features can be significant clinical challenges to manage.

Craniopharyngiomas can be treated by the trans-sphenoidal route but surgery may also involve a craniotomy, with a relatively high risk of hypothalamic damage and other complications. If the tumour has a large cystic component, it may be safer to place in the cyst cavity a drain that is attached to a subcutaneous access device, rather than attempt a resection. Whatever form it takes, surgery is unlikely to be curative and radiotherapy may often be given to reduce the risk of relapse. Unfortunately, craniopharyngiomas often recur, requiring repeated surgery. They often cause considerable morbidity, usually from hypothalamic obesity, water balance problems and/or visual failure.

**Diabetes insipidus**

This uncommon disorder is characterised by the persistent excretion of excessive quantities of dilute urine and by thirst. It is classified into two types:

- Cranial diabetes insipidus, in which there is deficient production of vasopressin by the hypothalamus
- Nephrogenic diabetes insipidus, in which the renal tubules are unresponsive to vasopressin.

The underlying causes are listed in Box 18.60.

**Clinical features**

The most marked symptoms are polyuria and polydipsia. The patient may pass 5–20 L or more of urine in 24 hours. This is of low specific gravity and osmolality. If the patient has an intact thirst mechanism, is conscious and has access to oral fluids, then he or she can maintain adequate fluid intake. However, in an unconscious patient or a patient with damage to the hypothalamic thirst centre, diabetes insipidus is potentially lethal. If there is associated cortisol deficiency, then diabetes insipidus may not be manifest until glucocorticoid replacement therapy is given.

The most common differential diagnosis is primary polydipsia, caused by drinking excessive amounts of fluid in the absence of a defect in vasopressin or thirst control.

---

**Box 18.60 Causes of diabetes insipidus**

**Cranial**
- Structural hypothalamic or high stalk lesion
  - See Box 18.54

**Idiopathic**
- Genetic defect
  - Dominant (AVP gene mutation)
  - Recessive (DIDMOAD syndrome – association of diabetes insipidus with diabetes mellitus, optic atrophy, deafness)

**Nephrogenic**
- Genetic defect
  - V2 receptor mutation
  - Aquaporin-2 mutation
  - Cystinosis
- Metabolic abnormality
  - Hypokalaemia
  - Hypercalcaemia

**Drug therapy**
- Lithium
- Demeclocycline

**Poisoning**
- Heavy metals

**Chronic kidney disease**
- Polycystic kidney disease
- Sickle-cell anaemia
- Infiltrative disease
18.61 How and when to do a water deprivation test

**Use**
- To establish a diagnosis of diabetes insipidus and to differentiate cranial from nephrogenic causes

**Protocol**
- No coffee, tea or smoking on the test day
- Free fluids until 0730 hrs on the morning of the test, but discourage patients from ‘stocking up’ with extra fluid in anticipation of fluid deprivation
- No fluids from 0730 hrs
- Attend at 0830 hrs for measurement of body weight and plasma and urine osmolality
- Record body weight, urine volume, plasma and urine osmolality and thirst score on a visual analogue scale every 2 hrs for up to 8 hrs
- Stop the test if the patient loses 3% of body weight
- If plasma osmolality reaches >300 mOsmol/kg and urine osmolality <600 mOsmol/kg, then administer DDAVP (see text) 2 μg IM

**Interpretation**
- Diabetes insipidus is confirmed by a plasma osmolality >300 mOsmol/kg with a urine osmolality <600 mOsmol/kg
- Cranial diabetes insipidus is confirmed if urine osmolality rises by at least 50% after DDAVP
- Nephrogenic diabetes insipidus is confirmed if DDAVP does not concentrate the urine
- Primary polydipsia is suggested by low plasma osmolality at the start of the test

**Investigations**

Diabetes insipidus can be confirmed if serum vasopressin is undetectable (although the assay for this is not widely available) or the urine is not maximally concentrated (i.e. <600 mmol/kg) in the presence of increased plasma osmolality (i.e. >300 mOsmol/kg). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in Box 18.61 is widely used, but an alternative is to infuse hypertonic (5%) saline and measure vasopressin secretion in response to increasing plasma osmolality. Thirst can also be assessed during this test on a visual analogue scale. Anterior pituitary function should be assessed before and after dehydration of patients with nephrogenic diabetes insipidus (see text). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in Box 18.61 is widely used, but an alternative is to infuse hypertonic (5%) saline and measure vasopressin secretion in response to increasing plasma osmolality. Thirst can also be assessed during this test on a visual analogue scale. Anterior pituitary function should be assessed before and after dehydration of patients with nephrogenic diabetes insipidus (see text). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in Box 18.61 is widely used, but an alternative is to infuse hypertonic (5%) saline and measure vasopressin secretion in response to increasing plasma osmolality. Thirst can also be assessed during this test on a visual analogue scale. Anterior pituitary function should be assessed before and after dehydration of patients with nephrogenic diabetes insipidus (see text). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in Box 18.61 is widely used, but an alternative is to infuse hypertonic (5%) saline and measure vasopressin secretion in response to increasing plasma osmolality. Thirst can also be assessed during this test on a visual analogue scale. Anterior pituitary function should be assessed before and after dehydration of patients with nephrogenic diabetes insipidus (see text).

In primary polydipsia, the urine may be excessively dilute because of chronic diabetes, which ‘washes out’ the solute gradient across the loop of Henle, but plasma osmolality is low rather than high. DDAVP (see below) should not be administered to patients with primary polydipsia, since it will prevent excretion of water and there is a risk of severe water intoxication if the patient continues to drink fluid to excess.

In nephrogenic diabetes insipidus, appropriate further tests may include plasma electrolytes, calcium, ultrasound of the kidneys and urinalysis.

**Management**

Treatment of cranial diabetes insipidus is with des-amino-des-aspartate-arginine vasopressin (desmopressin, DDAVP), an analogue of vasopressin that has a longer half-life. For chronic replacement therapy DDAVP may be administered intranasally and orally, although the latter formulation has variable bioavailability.

In sick patients, DDAVP should be given by intramuscular injection. The dose of DDAVP should be adjusted on the basis of serum sodium concentrations and/or osmolality. The principal hazard is excessive treatment, resulting in water intoxication and hyponatraemia. Conversely, inadequate treatment results in thirst and polyuria. The ideal dose prevents nocturia but allows a degree of polyuria from time to time before the next dose (e.g. DDAVP nasal dose 5 μg in the morning and 10 μg at night).

The polyuria in nephrogenic diabetes insipidus is improved by thiazide diuretics (e.g. bendroflumethiazide 5–10 mg/day), amiloride (5–10 mg/day) and NSAIDs (e.g. indometacin 15 mg 3 times daily), although the last of these carries a risk of reducing glomerular filtration rate.

18.62 The pituitary and hypothalamus in old age

- Late presentation: often with large tumours causing visual disturbance, because early symptoms such as amenorrhoea and sexual dysfunction do not occur or are not recognised.
- Coincidentally discovered pituitary tumours: may not require surgical intervention if the visual apparatus is not involved, because of slow growth.
- Hyperprolactinaemia: less impact in post-menopausal women who are already ‘physiologically’ hypogonadal. Macroadenomas, however, require treatment because of their potential to cause mass effects.

Disorders affecting multiple endocrine glands

**Multiple endocrine neoplasia**

Multiple endocrine neoplasias (MEN) are rare autosomal dominant syndromes characterised by hyperplasia and formation of adenomas or malignant tumours in multiple glands. They fall into four groups, as shown in Box 18.63. Some other genetic diseases also have an increased risk of endocrine tumours; for example, phaeochromocytoma is associated with von Hippel–Lindau syndrome (p. 1132) and neurofibromatosis type 1 (p. 1131).

The MEN syndromes should be considered in all patients with two or more endocrine tumours and in patients with solitary tumours who report other endocrine tumours in their family. Inactivating mutations in MEN 1 (MENIN), a tumour suppressor gene on chromosome 11, cause MEN 1, whereas MEN 2 and 3 (also known as MEN 2a and 2b, respectively) are caused by gain-of-function mutations in the RET proto-oncogene on chromosome 10. These cause constitutive activation of the membrane-associated tyrosine kinase RET, which controls the development of cells that migrate from the neural crest. In contrast, loss-of-function mutations of the RET kinase cause Hirschsprung’s disease (p. 834). MEN 4 is extremely rare and is associated with loss-of-function mutations in the CDKN1B gene on chromosome 12; this gene codes for the protein p27, which has putative tumour suppressor activity. Predictive genetic testing can be performed on relatives of individuals with MEN syndromes, after appropriate counselling (p. 59).

Individuals who carry mutations associated with MEN should be entered into a surveillance programme. In MEN 1, this typically involves annual history, examination and measurements of serum calcium and prolactin, and MRI of the pituitary and pancreas every 2 years; some centres also perform regular CT or MRI scans.
Further information

### Multiple endocrine neoplasia (MEN) syndromes

**MEN 1 (Wermer’s syndrome)**
- Primary hyperparathyroidism
- Pituitary tumours
- Pancreatic neuro-endocrine tumours (e.g. non-functioning, insulinoma, gastrinoma)
- Bronchial and thymic carcinoids
- Adrenal tumours
- Cutaneous lesions (e.g. lipomas, collagenomas, angiofibromas)

**MEN 2 (also known as MEN 2a or Sipple’s syndrome)**
- Primary hyperparathyroidism
- Medullary carcinoma of thyroid
- Phaeochromocytoma

**MEN 3 (also known as MEN 2b)**
- As for MEN 2 above (though medullary thyroid cancer occurs earlier, even within the first year of life)
- Marfanoid habitus
- Skeletal abnormalities (e.g. craniosynostosis)
- Abnormal dental enamel
- Multiple mucosal neuromas

**MEN 4**
- Primary hyperparathyroidism
- Pituitary tumours
- Possible tumours in the adrenals, reproductive organs, kidneys
- Possible pancreatic, gastric, bronchial and cervical neuro-endocrine tumours

### Autoimmune polyendocrine syndromes (APS)*

**Type 1 (APECED)**
- Addison’s disease
- Hypoparathyroidism
- Type 1 diabetes
- Primary hypothyroidism
- Chronic mucocutaneous candidiasis
- Nail dystrophy
- Dental enamel hypoplasia

**Type 2 (Schmidt’s syndrome)**
- Addison’s disease
- Primary hypothyroidism
- Graves’ disease
- Pernicious anaemia
- Primary hypogonadism
- Type 1 diabetes
- Vitiligo
- Coeliac disease
- Myasthenia gravis

*In both types of APS, the precise pattern of disease varies between affected individuals. (APECED = autoimmune poly-endocrinopathy-candidiasis-ectodermal dystrophy)

---

ofs the chest. In individuals with MEN 2 and 3, annual history, examination and measurement of serum calcium, calcitonin and urinary or plasma catecholamine metabolites should be performed. Because the penetrance of medullary carcinoma of the thyroid approaches 100% in individuals with a RET mutation, prophylactic thyroidectomy should be performed in early childhood in most patients. The precise timing of surgery in childhood should be guided by the specific mutation in the RET gene.

### Autoimmune polyendocrine syndromes

Two distinct autoimmune polyendocrine syndromes are known: APS types 1 and 2.

The most common is APS type 2 (Schmidt’s syndrome), which typically presents in women between the ages of 20 and 60. It is usually defined as the occurrence in the same individual of two or more autoimmune endocrine disorders, some of which are listed in Box 18.64. The mode of inheritance is autosomal dominant with incomplete penetrance and there is a strong association with HLA-DR3 and CTLA-4.

Much less common is APS type 1, which is also termed autoimmune poly-endocrinopathy-candidiasis-ectodermal dystrophy (APECED). This is inherited in an autosomal recessive fashion and is caused by loss-of-function mutations in the autoimmune regulator gene AIRE, which is responsible for the presentation of self-antigens to thymocytes in utero. This is essential for the deletion of thymocyte clones that react against self-antigens and hence for the development of immune tolerance (p. 82). The most common clinical features are described in Box 18.64, although the pattern of presentation is variable and other autoimmune disorders are often observed.

### Late effects of childhood cancer therapy

The therapies used to treat cancers in children and adolescents, including radiotherapy and chemotherapy, may cause long-term endocrine dysfunction (p. 1298).

Clinical assessment and investigation of nutritional status

Under-nutrition can go unnoticed in patients with multiple comorbidities. It is vital to be aware of under-nutrition as a potential reason for any acute medical presentation or as a modifier of it. Early nutritional assessment is crucial and a dietary history provides useful information (especially when taken by a dietitian). Points to note include past medical and surgical history (e.g. abdominal or intestinal surgery), a drug history and a specific diet history. Evidence of recent weight loss and muscle wasting should be sought. Simple, validated tools are available to screen patients for nutritional problems. Body composition reflects energy balance and is assessed by clinical anthropomorphic measurements. More sophisticated techniques may be used to assess body composition or functional capacity if required.

Important elements of the diet history

Ask about weight

- Current weight
- Weight 2 weeks, 1 month and 6 months ago
- Assessment of degree of change

Ask about current food intake

- Quantity of food and any change
- Quality of food taken
- Whether normal food is being eaten
- Avoidance of specific food types (e.g. solids)
- Any nutritional supplements
- Reliance on supplements/tube feeding
- Any change in appetite or interest in food
- Any taste disturbance

Ask about symptoms that interfere with eating

- Oral ulcers or oral pain
- Difficulties swallowing
- Nausea/vomiting
- Early satiety
- Alteration in bowel habit
- Abdominal (or other) pain

Ask about activity levels/performance status

- Normal activity
- Slightly reduced activity
- Inactive <50% of the time
- Inactive most of the time

Body mass index (BMI)

\[
\text{BMI} = \frac{\text{wt (kg)}}{\text{ht (m)}^2}
\]

Example: an adult of 70 kg with a height of 1.75 m has a BMI of 70/1.75^2 = 22.9 kg/m^2

- BMI is a useful way of identifying under- or over-nutrition but cannot discriminate between lean body or muscle mass and fat mass
- Fat mass is also subject to ethnic variation; for the same BMI, Asians tend to have more body fat than Europeans

If height cannot be determined (e.g. in older people or those unable to stand), measurement of the femoral length or ‘knee height’ is a good surrogate

Body fat content and muscle mass

- Triceps skinfold thickness (when combined with mid-/upper arm circumference estimates muscle mass)

Screening hospitalised patients for risk of malnutrition. Acute illnesses include decompensated liver disease, cancer cachexia or being kept ‘nil by mouth’. Adapted from the British Association of Parenteral and Enteral Nutrition Malnutrition Universal Screening Tool (www.bapen.org.uk).
Nutritional factors and disease

Obtaining adequate nutrition is a fundamental requirement for the survival of every individual and species. The politics of food provision for humans are complex and constitute a prominent factor in wars, natural disasters and the global economy. In recent decades, economic success has been rewarded by plentiful nutrition unknown to previous generations, which has led to a pandemic of obesity and its consequences for health, yet in many parts of the world, famine and under-nutrition still represent a huge burden. Quality, as well as quantity, of food influences health, with governmental advice on healthy diets maximising fruit and vegetable intakes (Fig. 19.1). Inappropriate diets have been linked to diseases such as coronary heart disease and cancer. Deficiencies of vitamins or minerals lead to avoidable deaths, anaemia due to iron deficiency or blindness due to severe vitamin A deficiency. A proper understanding of nutrition is therefore essential in dealing with the needs of individual patients and in informing the planning of public policy.

Physiology of nutrition

Nutrients in the diet can be classified into ‘macronutrients’, which are eaten in relatively large amounts to provide fuel for energy, and ‘micronutrients’ (e.g. vitamins and minerals), which do not contribute to energy balance but are required in small amounts because they are not synthesised in the body.

Energy balance

The laws of thermodynamics dictate that energy balance is achieved when energy intake = energy expenditure (Fig. 19.2). Energy expenditure has several components. The basal metabolic rate (BMR) describes the obligatory energy expenditure required to maintain metabolic functions in tissues and hence sustain life. It is most closely predicted by fat-free mass (i.e. total body mass minus fat mass), which is lower in females and older people (Fig. 19.2B). Extra metabolic energy is consumed during growth, pregnancy and lactation, and when febrile. Metabolic energy is also required for thermal regulation, and expenditure is higher in cold or hot environments. The energy required for digestion of food (diet-induced thermogenesis; Fig. 19.2D) accounts for approximately 10% of total energy expenditure, with protein requiring more energy than other macronutrients. Another component of energy expenditure is governed by the level of muscular activity, which can vary considerably with occupation and lifestyle (Fig. 19.2C). Physical activity levels are usually defined as multiples of BMR. Energy intake is determined by the ‘macronutrient’ content of food. Carbohydrates, fat, protein and alcohol provide fuel for oxidation in the mitochondria to generate energy (as adenosine triphosphate (ATP); p. 49). The energy provided by each of these elements differs:

- carbohydrates (16 kJ/g)
- fat (37 kJ/g)
- protein (17 kJ/g)
- alcohol (29 kJ/g).

Regulation of energy balance

Energy intake and expenditure are highly regulated (Fig. 19.3). A link with reproductive function ensures that pregnancy is most likely to occur during times of nutritional plenty, when both mother and baby have a better chance of survival. Improved nutrition is thought to be the reason for the increasingly early onset of puberty in many societies. At the other extreme, anorexia nervosa and excessive exercise can lead to amenorrhoea (p. 654).

Regulation of energy balance is coordinated in the hypothalamus, which receives afferent signals that indicate nutritional status in the short term (e.g. the stomach hormone ghrelin, which falls immediately after eating and rises gradually thereafter, to suppress satiety and signal that it is time for the next meal) and the long term (e.g. the adipose hormone leptin, which increases with growing fat mass and may also link fat mass to reproductive function). The hypothalamus responds with changes in many local neurotransmitters that alter activity in a number of pathways that influence energy balance (Fig. 19.3), including hormones acting on the pituitary gland (see Fig. 18.2, p. 633), and neural control circuits that connect with the cerebral cortex and autonomic nervous system.

Responses to under- and over-nutrition

These complex regulatory pathways allow adaptation to variations in nutrition. In response to starvation, reproductive function is suppressed, BMR is reduced, and there are profound psychological effects, including energy conservation through lethargy. These adjustments can ‘defend’ body weight within certain limits. In the low-insulin state of starvation (see Fig. 20.5, p. 725), however, fuels are liberated from stores initially in glycogen (in liver and muscle), then in triglyceride (lipolysis in adipose tissue, with excess free fatty acid supply to the liver leading to ketosis) and finally in protein (proteolysis in muscle). In those with a high glucose requirement, such as neonates and women who are pregnant or breastfeeding, starvation can result in ketoacidosis associated with normal or low blood glucose (p. 365).

In response to over-nutrition, BMR is increased, and extra energy is consumed in the work of carrying increased fat stores, so that body weight is again ‘defended’ within certain limits. In the high-insulin state of over-nutrition, excess energy is invested in fatty acids and stored as triglycerides; these are deposited principally in adipose tissue but they may also accumulate in the liver (non-alcoholic fatty liver disease; p. 882) and skeletal muscle. If hypothalamic function is abnormal (e.g. in those with...
Nutritional factors and disease

Carbohydrates

Types of carbohydrate and their dietary sources are listed in Box 19.1. The ‘available’ carbohydrates (starches and sugars) are broken down to monosaccharides before absorption from the gut (p. 768), and supply over half the energy in a normal, well-balanced diet (see Fig. 19.2A). No individual carbohydrate is an essential nutrient, as carbohydrates can be synthesised de novo from glycerol or protein. If the available carbohydrate intake is less than 100 g per day, however, increased lipolysis leads to ketosis (see Fig. 20.7, p. 730).

Dietary guidelines do not restrict the intake of intrinsic sugars in fruit and vegetables or the sugars in milk. However, intake of non-milk extrinsic sugars (sucrose, maltose, fructose), which increase the risk of dental caries and diabetes mellitus, should...

be limited. Individuals who do not produce lactase (‘lactose-intolerant’) are advised to avoid or limit dairy products and foods with added lactose. Starches in cereal foods, root foods and legumes provide the largest proportion of energy in most diets around the world. All starches are polymers of glucose, linked by the same 1–4 glycosidic linkages. Some starches are digested promptly by salivary and then pancreatic amylase, however, producing rapid delivery of glucose to the blood. Other starches are digested more slowly, either because they are protected in the structure of the food, or because of their crystal structure, or because the molecule is unbranched (amylose). These differences are the basis for the ‘glycaemic index’ of foods. This is the area under the curve of the rise in blood glucose concentration in the 2 hours following ingestion of 50 g carbohydrate, expressed as a percentage of the response to 50 g anhydrous glucose. There is evidence linking high glycaemic index foods, particularly foods containing large amounts of sugars such as glucose, sucrose or fructose (e.g. in soft drinks) with obesity and type 2 diabetes.
Dietary fibre

Dietary fibre is plant food that is not digested by human enzymes in the gastrointestinal tract. Most dietary fibre is known as ‘non-starch polysaccharides’ (NSPs) (see Box 19.1). A small percentage of ‘resistant’ dietary starch may also pass unchanged into the large intestine. Dietary fibre can be broken down by the resident bacteria in the colon to produce short-chain fatty acids. This is essential fuel for the enterocytes and contributes to bowel health. The extent of flatus formed is dependent on the food source.

Some types of NSP, notably the hemicellulose of wheat, increase the water-holding capacity of colonic contents and the bulk of faeces. They relieve simple constipation, appear to prevent diverticulosis and may reduce the risk of cancer of the colon. Other viscous, indigestible polysaccharides like pectin and guar gum are important in the upper gastrointestinal tract, where they slow gastric emptying, contribute to satiety, and reduce bile salt absorption and hence plasma cholesterol concentration.

Fats

Fat has the highest energy density of the macronutrients (37 kJ/g) and excessive consumption may be an insidious cause of obesity. Free fatty acids are absorbed in chylomicrons and excessive consumption may be an insidious cause of obesity. Fat has the highest energy density of the macronutrients (37 kJ/g) and excessive consumption may be an insidious cause of obesity.

Cholesterol is also absorbed directly from food in chylomicrons and is an important substrate for steroid and sterol synthesis, but not an important source of energy.

Proteins

Proteins are made up of some 20 different amino acids, of which nine are ‘essential’ (Box 19.2), i.e. they cannot be synthesised in humans but are required for synthesis of important proteins. Another group of five amino acids are termed ‘conditionally essential’, meaning that they can be synthesised from other amino acids, provided there is an adequate dietary supply. The remaining amino acids can be synthesised in the body by transamination, provided there is a sufficient supply of amino groups.

The nutritive or ‘biological’ value of different proteins depends on the relative proportions of essential amino acids they contain. Proteins of animal origin, particularly from eggs, milk and meat, are generally of higher biological value than proteins of vegetable origin, which are low in one or more of the essential amino acids. When two different vegetable proteins are eaten together (e.g. a cereal and a legume), however, their amino acid contents are complementary and produce an adequate mix, an important principle in vegan diets.

Dietary recommendations for macronutrients

Recommendations for energy intake (Box 19.3) and proportions of macronutrients (Box 19.4) have been calculated to provide a balance of essential nutrients and minimise the risks of excessive refined sugar (dental caries, high glycaemic index/diabetes mellitus), saturated fat or trans fat (obesity, coronary heart disease). Recommended dietary fibre intake is based on avoiding risks of colonic disease. The usual recommended protein intake for a healthy man doing light work is 65–100 g/day. The minimum requirement is around 40 g of protein with a high proportion of essential amino acids or a high biological value.

Nutritional factors and disease  •  697

19

19.2 Amino acids

Essential amino acids

- Tryptophan
- Histidine
- Methionine
- Threonine
- Isoleucine
- Leucine
- Lysine
- Phenylalanine

Conditionally essential amino acids and their precursors

- Cysteine: methionine, serine
- Tyrosine: phenylalanine
- Arginine: glutamine/glutamate, aspartate
- Proline: glutamate
- Glycine: serine, choline

(p. 932). Sugar alcohols (e.g. sorbitol) that are not absorbed form the gut and are used as replacement sweeteners can cause diarrhoea if eaten in large amounts.
Disorders of altered energy balance

Obesity

Obesity is regarded as a pandemic, with potentially disastrous consequences for human health. Over 25% of adults in the UK were obese (i.e. BMI ≥ 30 kg/m²) in 2015, compared with 7% in 1980 and 16% in 1995. Moreover, almost 66% of the UK adult population are overweight (BMI ≥ 25 kg/m²), although there is considerable regional and age group variation. In developing countries, average national rates of obesity are low, but these figures may disguise high rates of obesity in urban communities; for example, nearly 25% of women in urban India are overweight.

There is increasing public awareness of the health implications of obesity. Many will seek medical help for their obesity, others will present with complications of obesity, and increasing numbers are being identified during health screening examinations.

Complications

Obesity has adverse effects on both mortality and morbidity (Fig. 19.5). Changes in mortality are difficult to analyse due to the confounding effects of lower body weight in cigarette smokers and those with other illnesses (such as cancer). It is clear, however, that the lowest mortality rates are seen in Europeans in the BMI range 18.5–24 kg/m² (and at lower BMI in Asians). It is suggested that obesity at age 40 years can reduce life expectancy by up to 7 years for non-smokers and by 13 years for smokers. Coronary heart disease (Fig. 19.6) is the major cause of death but cancer rates are also increased in the overweight, especially colorectal cancer in males and cancer of the gallbladder, biliary tract, breast, endometrium and cervix in females. Obesity has little effect on life expectancy above 70 years of age, but the obese do spend a greater proportion of their active life disabled.

Fig. 19.5 Complications of obesity.
rise in obesity has been accompanied by an epidemic of type 2 diabetes (p. 732) and osteoarthritis, particularly of the knee. Although an increased body size results in greater bone density through increased mechanical stress, it is not certain whether this translates to a lower incidence of osteoporotic fractures (p. 1044).

Obesity may have profound psychological consequences, compounded by stigmatisation of the obese in many societies.

**Body fat distribution**

For some complications of obesity, the distribution rather than the absolute amount of excess adipose tissue appears to be important. Increased intra-abdominal fat causes ‘central’ (‘abdominal’, ‘visceral’, ‘android’ or ‘apple-shaped’) obesity, which contrasts with subcutaneous fat accumulation causing ‘generalised’ (‘gynoid’ or ‘pear-shaped’) obesity; the former is more common in men and is more closely associated with type 2 diabetes, the metabolic syndrome and cardiovascular disease (see Fig. 19.5). The key difference between these depots of fat may lie in their vascular anatomy, with intra-abdominal fat draining into the portal vein and thence directly to the liver. Thus many factors that are released from adipose tissue (including free fatty acids; ‘adipokines’, such as tumour necrosis factor alpha, adiponectin and resistin) may be at higher concentration in the liver and muscle, and hence induce insulin resistance and promote type 2 diabetes. Recent research has also highlighted the importance of fat deposition within specific organs, especially the liver, as an important determinant of metabolic risk in the obese.

**Aetiology**

Accumulation of fat results from a discrepancy between energy consumption and energy expenditure that is too large to be defended by the hypothalamic regulation of BMR. A continuous small daily positive energy balance of only 0.2–0.8 MJ (50–200 kcal; <10% of intake) would lead to weight gain of 2–20 kg over a period of 4–10 years. Given the cumulative effects of subtle energy excess, body fat content shows ‘tracking’ with age, such that obese children usually become obese adults. Weight tends to increase throughout adult life, as BMR and physical activity decrease (see Fig. 19.2).

The pandemic of obesity reflects changes in both energy intake and expenditure (Box 19.5), although both are difficult to measure reliably. The estimated average global daily supply of food energy per person increased from approximately 9.8 MJ (2350 kcal) in the 1960s to approximately 11.7 MJ (2800 kcal) in the 1990s, but its delivery is unequal. For example, in India it is estimated that 5% of the population receives 40% of the available food energy, leading to obesity in the urban population in parallel with under-nutrition in some rural communities. In affluent societies, a significant proportion of this food supply is discarded.

In the USA, men’s average daily energy intake reportedly rose from 10.2 MJ (2450 kcal) in 1971 to 11.0 MJ (2618 kcal) in 2000. Portion sizes, particularly of energy-dense foods such as drinks with highly refined sugar content and salty snacks, have increased. However, UK data suggest that energy intakes have declined (which may in part be due to deliberate restriction or ‘dieting’), but this is apparently insufficient to compensate for the decrease in physical activity in recent years. Obesity is correlated positively with the number of hours spent watching television, and inversely with levels of physical activity (e.g. stair climbing). It is suggested that minor activities such as fidgeting, also termed non-exercise activity thermogenesis (NEAT), may contribute to energy expenditure and protect against obesity.

**Susceptibility to obesity**

Susceptibility to obesity and its adverse consequences undoubtedly varies between individuals. It is not true that obese subjects have a ‘slow metabolism’, since their BMR is higher than that of lean subjects. Twin and adoption studies confirm a genetic influence on obesity. The pattern of inheritance suggests a polygenic disorder, with small contributions from a number of different genes, together accounting for 25–70% of variation in weight. Recent results from ‘genome-wide’ association studies of polymorphisms in large numbers of people (p. 45) have
identified a handful of genes that influence obesity, some of which encode proteins known to be involved in the control of appetite or metabolism and some of which have an unknown function. These genes account for less than 5% of the variation in body weight, however. Genes also influence fat distribution and therefore the risk of the metabolic consequences of obesity, such as type 2 diabetes and fatty liver disease.

A few rare single-gene disorders have been identified that lead to severe childhood obesity. These include mutations of the melanocortin-4 receptor (MC4R), which account for approximately 5% of severe early-onset obesity; defects in the enzymes processing propiopimelancortin (POMC, the precursor for adrenocorticotropic hormone (ACTH)) in the hypothalamus; and mutations in the leptin gene (see Fig. 19.5). The latter can be treated by leptin injections. Additional genetic conditions in which obesity is a feature include Prader–Willi (see Box 3.8, p. 51) and Lawrence–Moon–Biedl syndromes.

Reversible causes of obesity and weight gain

In a small minority of patients presenting with obesity, specific causal factors can be identified and treated (Box 19.6). These patients are distinguished from those with idiopathic obesity by their short history, with a recent marked change in the trajectory of their adult weight gain.

Clinical features and investigations

In assessing an individual presenting with obesity, the aims are to:

- quantify the problem
- exclude an underlying cause
- identify complications
- reach a management plan.

Severity of obesity can be quantified using the BMI and waist circumference. The risk of metabolic and cardiovascular complications of obesity is higher in those with a high waist circumference; lower levels of BMI and waist circumference indicate higher risk in Asian populations (Box 19.7).

A dietary history may be helpful in guiding dietary advice (p. 693) but is notoriously susceptible to under-reporting of food consumption. It is important to consider ‘pathological’ eating behaviour (such as binge eating, nocturnal eating or bulimia; p. 1204), which may be the most important issue to address in some patients. Alcohol is an important source of energy intake and should be considered in detail.

The history of weight gain may help diagnose underlying causes. A patient who has recently gained substantial weight or has gained weight at a faster rate than previously, and is not taking relevant drugs (see Box 19.9), is more likely to have an underlying disorder such as hypothyroidism (p. 639) or Cushings’s syndrome (p. 666). All obese patients should have thyroid function tests performed on one occasion, and an overnight dexamethasone suppression test or 24-hour urine free cortisol if Cushing’s syndrome is suspected. Monogenic and ‘syndromic’ causes of obesity are usually relevant only in children presenting with severe obesity.

Assessment of the diverse complications of obesity (see Fig. 19.5) requires a thorough history, examination and screening investigations. The impact of obesity on the patient’s life and work is a major consideration. Assessment of other cardiovascular risk factors is important. Blood pressure should be measured with a large cuff, if required (p. 510). Associated type 2 diabetes and dyslipidaemia are detected by measurement of blood glucose and HbA1c and a serum lipid profile, ideally in a fasting morning sample. Elevated serum transaminases occur in patients with non-alcoholic fatty liver disease (p. 884).

Management

The health risks of obesity are largely reversible if identified and treated early. Interventions proven to reduce weight in obese patients also ameliorate cardiovascular risk factors. Lifestyle advice that lowers body weight and increases physical exercise reduces the incidence of type 2 diabetes (p. 743). Given the high prevalence of obesity and the large magnitude of its risks, population strategies to prevent and reverse obesity are high on the public health priority list for many countries. Initiatives include promoting healthy eating in schools, enhancing walking

---

**Endocrine factors**

- Hypothyroidism
- Cushing’s syndrome
- Insulinoma
- Hypothalamic tumours or injury

**Drug treatments**

- Atypical antipsychotics (e.g. olanzapine)
- Sulphonylureas, thiazolidinediones, insulin
- Pizotifen
- Glucocorticoids
- Sodium valproate
- β-blockers

¹Classification of the World Health Organisation (WHO) and International Obesity Task Force. The Western Pacific Region Office of WHO recommends that, among Asians, BMI >23.0 is overweight and >25.0 is obese. Lower cut-offs for waist circumference have also been proposed for Asians but have not been validated. ²When BMI is >35 kg/m², waist circumference does not add to the increased risk.
and cycling options for commuters, and liaising with the food industry to reduce energy, sugar and fat content and to label foods appropriately; taxes on high-sugar drinks have also been introduced in some countries. Unfortunately, ‘low-fat’ foods are often still energy-dense, and current lifestyles with labour-saving devices, sedentary work and passive leisure activities have much lower energy requirements than the manual labour and household duties of previous generations.

Most patients seeking assistance with obesity are motivated to lose weight but have attempted to do so previously without long-term success. Often weight will have oscillated between periods of successful weight loss and then regain of weight. These patients may hold misconceptions that they have an underlying disease, inaccurate perceptions of their energy intake and expenditure, and an unrealistic view of the target weight that they would regard as a ‘success’. An empathetic explanation of energy balance, which recognises that some individuals are more susceptible to obesity than others and may find it more difficult to lose body weight and sustain this loss, is important. Exclusion of underlying ‘hormone imbalance’ with simple tests is reassuring and shifts the focus on to consideration of energy balance. Appropriate goals for weight loss should be agreed, recognising that the slope of the relationship between obesity and many of its complications becomes steeper with increasing BMI, so that a given amount of weight loss achieves greater risk reduction at higher levels of BMI. A reasonable goal for most patients is to lose 5–10% of body weight.

The management plan will vary according to the severity of the obesity (see Box 19.7) and the associated risk factors and complications. It will also be influenced by availability of resources; health-care providers and regulators have generally been careful not to recommend expensive interventions (especially long-term drug therapy and surgery) for everyone who is overweight. Instead, not to recommend expensive interventions (especially long-term health-care providers and regulators have generally been careful not to recommend expensive interventions (especially long-term drug therapy and surgery) for everyone who is overweight. Instead, most guidelines focus resources on short-term interventions in those who have high health risks and comorbidities associated with their obesity, and who have demonstrated their capacity to alter their lifestyle to achieve weight loss (Fig. 19.7).

Lifestyle advice

Behavioural modification to avoid some of the effects of the ‘obesogenic’ environment (see Box 19.5) is the cornerstone of long-term control of weight. Adopting regular eating patterns and maximising physical activity are advised, with reference to the modest extra activity required to increase physical activity level (PAL) ratios (see Fig. 19.2C). Where possible, this should be incorporated in the daily routine (e.g. walking rather than driving to work), as this is more likely to be sustained. Alternative exercise (e.g. swimming) may be considered if musculoskeletal complications prevent walking. Changes in eating behaviour (including food selection, portion size control, avoidance of snacking, regular meals to encourage satiety, and substitution of sugar with artificial sweeteners) should be discussed. Regular support from a dietitian or attendance at a weight loss group may be helpful.

Weight loss diets

In overweight people, adherence to the lifestyle advice given above may gradually induce weight loss. In obese patients, more active intervention is usually required to lose weight before conversion to the ‘weight maintenance’ advice given above. A significant industry has developed in marketing diets for weight loss. These vary substantially in their balance of macronutrients (Box 19.8) but there is little evidence that they vary in their medium-term (1-year) efficacy. Most involve recommending a reduction of daily total energy intake of ~2.5 MJ (600 kcal) from the patient’s normal consumption. Modelling data that take into account the reduced energy expenditure as weight is lost suggest that a reduction of energy intake of 100 kJ per day will lead to an eventual body weight change of about 1 kg, with half of the weight change being achieved in about 1 year and 95% of the weight change in about 3 years. Weight loss is highly variable and patient adherence is the major determinant of success. There is some evidence that weight loss diets are most effective in their early weeks and that adherence is improved by novelty of the diet; this provides some justification for switching to a different dietary regimen when weight loss slows on the first diet. Disorders of altered energy balance • 701
supplementation is wise in those diets in which macronutrient balance is markedly disturbed.

In some patients, more rapid weight loss is required, e.g. in preparation for surgery. There is no role for starvation diets, which risk profound loss of muscle mass and the development of arrhythmias (and even sudden death) secondary to elevated free fatty acids, ketosis and deranged electrolytes. Very-low-calorie diets (VLCDs) can be considered for short-term rapid weight loss, producing losses of 1.5–2.5 kg/week, compared to 0.5 kg/week on conventional regimens, but require the supervision of an experienced physician and nutritionist. The composition of the diet should ensure a minimum of 50 g of protein each day for men and 40 g for women to minimise muscle degradation. Energy content should be a minimum of 1.65 MJ (400 kcal) for women of height <1.73 m, and 2.1 MJ (500 kcal) for all men and for women taller than 1.73 m. Side-effects are a problem in the early stages and include orthostatic hypotension, headache, diarrhoea and nausea.

Drugs

A huge investment has been made by the pharmaceutical industry in finding drugs for obesity. The side-effect profile has limited the use of many agents, with notable withdrawals from clinical use of sibutramine (increased cardiovascular events) and rimonabant (psychiatric side-effects) in recent years. Orlistat has been available for many years, and four drugs or drug combinations have recently been approved in the USA and two of these in Europe. There is no role for diuretics, or for thyroxine therapy without biochemical evidence of hypothyroidism. Drug therapy should always be used as an adjunct to lifestyle advice and support, which should be continued throughout treatment.

Orlistat inhibits pancreatic and gastric lipases and thereby decreases the hydrolysis of ingested triglycerides, reducing dietary fat absorption by approximately 30%. The drug is not absorbed and adverse side-effects relate to the effect of the resultant fat malabsorption on the gut: namely, loose stools, oily spotting, faecal urgency, flatus and the potential for malabsorption of fat-soluble vitamins. Orlistat at the standard dose of 120 mg is taken with each of the three main meals of the day; a lower dose (60 mg) is available without prescription in some countries. Its efficacy is shown in Figure 19.8; these effects may be explained because patients taking orlistat adhere better to low-fat diets in order to avoid unpleasant gastrointestinal side-effects.

The combination of low-dose phentermine and topiramate extended release has been approved in the USA; this results in weight loss of approximately 6% greater than placebo and benefits lipids and glucose concentrations. Concerns over teratogenicity of topiramate and cardiovascular effects of phentermine have so far

![Fig. 19.8 Effects of orlistat (A), liraglutide (B) and bariatric surgery (C) on weight loss.](image-url)

precluded its approval in Europe. The 5-HT₂c inhibitor lorcaserin is also approved in the USA; it is moderately effective and has a relatively low rate of adverse effects. The combination of the opioid antagonist naltrexone and the noradrenaline (norepinephrine)/dopamine re-uptake inhibitor bupropion is also effective. The main adverse effects are dry mouth and constipation. Finally, a higher dose of the injectable glucagon-like peptide-1 (GLP-1) receptor agonist liraglutide (3 mg) is also approved for use and has been shown to reduce the risk of diabetes in patients with pre-diabetes.

Drug therapy is usually reserved for patients with high risk of complications from obesity (see Fig. 19.7), and its optimum timing and duration are controversial. There is evidence that those patients who demonstrate early weight loss (usually defined as 5% after 12 weeks on the optimum dose) achieve greater and longer-term weight loss, and this is reflected in most guidelines for the use of drugs for obesity. Treatment can be stopped in non-responders at this point and an alternative treatment considered. Although life-long therapy is advocated for many drugs that reduce risk on the basis of relatively short-term research trials (e.g. drugs for hypertension and osteoporosis), some patients who continue to take anti-obesity drugs tend to regain weight with time; this may partly reflect age-related weight gain, but significant weight gain should prompt reinforcement of lifestyle advice and, if this is unsuccessful, drug therapy should be discontinued (see Fig. 19.8).

Surgery

‘Bariatric’ surgery is by far the most effective long-term treatment for obesity (see Fig. 19.8 and Box 19.9) and is the only anti-obesity intervention that has been associated with reduced mortality. Bariatric surgery should be contemplated in motivated patients who have very high risks of complications of obesity (see Fig. 19.7), when extensive dietary and drug therapy has been insufficiently effective. It is usually reserved for those with severe obesity (BMI >40 kg/m²), or those with a BMI >35 kg/m² and significant complications, such as type 2 diabetes or obstructive sleep apnoea, although some evidence-based guidelines now suggest surgery can be considered at a lower weight in people with recent-onset diabetes and a BMI >30 kg/m². Only experienced specialist surgeons should undertake these procedures, in collaboration with a multidisciplinary team. Several approaches are used (Fig. 19.9) and all can be performed laparoscopically. The mechanism of weight loss may not simply relate to limiting the stomach or absorptive capacity, but rather in disrupting the release of ghrelin from the stomach or promoting the release of other peptides from the small bowel, thereby enhancing satiety signalling in the hypothalamus. Diabetes may improve rapidly

after surgery, particularly after gastric bypass, and although this may be attributed to severe energy restriction in the perioperative period, it is possible that increased release of incretin hormones such as GLP-1 may contribute to the improvement in glucose control. Complications depend on the approach. Mortality is low in experienced centres but post-operative respiratory problems, wound infection and dehiscence, staple leaks, stomal stenosis, marginal ulcers and venous thrombosis may occur. Additional problems may arise at a later stage, such as pouch and distal oesophageal dilatation, persistent vomiting, ‘dumping’ (p. 801), hypoglycaemia and micronutrient deficiencies, particularly of folate, vitamin B₁₂ and iron, which are of special concern to women contemplating pregnancy; this should be delayed for at least 2 years following surgery.

Cosmetic surgical procedures may be considered in obese patients after successful weight loss. Apronectomy is usually advocated to remove an overhang of abdominal skin, especially if infected or ulcerated. This operation is of no value for long-term weight reduction if food intake remains unrestricted.

Treatment of additional risk factors

Obesity must not be treated in isolation and other risk factors must be addressed, including smoking, excess alcohol consumption, diabetes mellitus, hyperlipidaemia, hypertension and obstructive sleep apnoea. Treatment of these is discussed in the relevant chapters.

Under-nutrition

Starvation and famine

There remain regions of the world, particularly rural Africa, where under-nutrition due to famine is endemic; the prevalence of BMI of less than 18.5 kg/m² (Box 19.10) in adults is as high as 20%, and growth retardation due to under-nutrition affects 50% of children. The World Health Organisation (WHO) reports that chronic under-nutrition is responsible for more than half of all childhood deaths worldwide. Starvation is manifest as marasmus (malnutrition with marked muscle wasting) or, when additive complications such as oxidative stress come into play, malnourished children can develop kwashiorkor (malnutrition with oedema). Growth retardation is due to deficiencies of key nutrients (protein, zinc, potassium, phosphate and sulphur). Treatment of these childhood conditions is not discussed in this adult medical textbook. In adults, starvation is the result of chronic sustained negative energy (calorie) balance. Causes are shown in Box 19.11. Causes of weight loss are considered further on page 785.

Clinical features

In starvation, the severity of malnutrition can be assessed by anthropometric measurements, such as BMI (see p. 693 and Box 19.10). Demispan and mid-arm circumference measurements are most useful in monitoring progress during treatment. The clinical features of severe under-nutrition in adults are listed in Box 19.12. Under-nutrition often leads to vitamin deficiencies, especially of thiamin, folate and vitamin C (see below). Diarrhoea can lead to depletion of sodium, potassium and magnesium. The high mortality rate in famine situations is often due to outbreaks of infection, such as typhus or cholera, but the usual signs of infection may not be apparent. In advanced starvation, patients become completely inactive and may assume a flexed, fetal position. In the last stage of starvation, death comes quietly and often quite suddenly. The very old are most vulnerable. All organs are atrophied at necropsy, except the brain, which tends to maintain its weight.

Investigations

In a famine, laboratory investigations may be impractical but will show that plasma free fatty acids are increased and there is ketosis and a mild metabolic acidosis. Plasma glucose is low.
but albumin concentration is often maintained because the liver still functions normally. Insulin secretion is diminished, glucagon and cortisol tend to increase, and reverse T3 replaces normal triiodothyronine (p. 634). The resting metabolic rate falls, partly because of reduced lean body mass and partly because of hypothalamic compensation (see Fig. 19.2). The urine has a fixed specific gravity and creatinine excretion becomes low. There may be mild anaemia, leucopenia and thrombocytopenia. The erythrocyte sedimentation rate is normal unless there is infection. Tests of delayed skin hypersensitivity, e.g. to tuberculin, are falsely negative. The electrocardiogram shows sinus bradycardia and low voltage.

**Management**

Whether in a famine or in wasting secondary to disease, the severity of under-nutrition is graded according to BMI (see Box 19.10). People with mild starvation are in no danger; those with moderate starvation need extra feeding; and those who are severely underweight need hospital care.

In severe starvation, there is atrophy of the intestinal epithelium and of the exocrine pancreas, and the bile is dilute. It is critical for the condition to be managed by experts. When food becomes available, it should be given by mouth in small, frequent amounts if similar circumstances prevail. If food is distributed on the basis of need. Lastly, plans must be made for the future for prevention and/or earlier intervention if similar circumstances prevail.

### Under-nutrition in hospital

It is a paradox that, in spite of record levels of access to food in the developed economies of the world, under-nutrition remains a serious issue in many sectors of society, particularly the elderly and less independent. While the scale of the problem does not match that seen in the developing world, the issues pertaining to poor or impaired health are similar. In the general UK population, 30% of those requiring acute admission to hospital show evidence of serious under-nutrition and 65% of those admitted will lose an average of 5% of their total body weight during that admission. In the older population, levels of under-nutrition and vitamin deficiencies parallel levels of independent living. In Scotland, 33% of those aged over 65 who are living in their own home are deficient in folic acid and 10% are deficient in vitamin C. The prevalence of vitamin deficiencies rises further in less independent groups in residential or nursing homes.

Under-nutrition is poorly recognised in hospitals and has serious consequences. Physical effects include impaired immunity and muscle weakness, which in turn affect cardiac and respiratory function, and delayed wound healing after surgery with increased risks of post-operative infection. The under-nourished patient is often withdrawn and this may be mistaken for depressive illness. Engagement with treatment and rehabilitation can be adversely affected. Much of this can be avoided through better awareness of the prevalence of under-nutrition, prompt nutritional assessment and monitoring with appropriate intervention. Scoring systems, such as the MUST tool (p. 693), raise awareness across multidisciplinary teams, and encourage staff to assess and monitor food intake and weigh patients regularly.

Causes are often complex (see Box 19.11). Social issues impact on food choices and may cause or exacerbate disease. Social isolation, low levels of disposable income and a lack of knowledge or interest in healthy eating may increase reliance on calorie-dense convenience foods of poor nutritional quality. In turn, the non-specific effects of chronic inflammation, infection or malignancy, as well as specific gastrointestinal disorders, may adversely affect appetite, reducing food intake. Patients may report avoidance of certain foods that exacerbate their symptoms (often fibre-rich, otherwise healthy foods).

A loss of appetite is not specific to gastrointestinal disease and may be seen as a non-specific response to myriad other conditions or their treatments. The most common reported side-effects...
of many prescription drugs are nausea and gastrointestinal disturbance. Surgical resection of the gastrointestinal tract can have major nutritional sequelae in the years following, ranging from intolerance of normal volumes of food to intestinal failure (where there is partial or complete failure of the intestine to perform its vital functions). There may be no single problem impacting on the intake of adequate nutrition but it helps to consider systematically where the problem(s) might lie (Box 19.15).

### Specific issues arising after intestinal surgery

**Gastrectomy or partial gastrectomy**

There may be a loss of gastric capacity, leading to intolerance of larger volumes of food and early satiety or vomiting. Vagotomy and gastroenterostomy may cause symptoms of dumping syndrome (p. 801), which can lead to food avoidance and weight loss. Many patients who have had gastric surgery will develop iron deficiency (and, less commonly, vitamin D and vitamin B₁₂ deficiency) unless adequately supplemented post-operatively.

**Proximal small bowel surgery**

Those who have had roux-en-Y reconstruction or have blind-ending or excluded loops of small bowel are prone to small intestinal bacterial overgrowth. This may impair absorption of iron, folic acid and vitamin B₁₂. Very rarely, it can cause hyperammonaemia and metabolic coma, in which bacterial metabolism of amino acids leads to a lack of citrulline and impairment of the urea cycle.

**Pancreatic resection/Whipple’s operation**

Without adequate post-operative supplementation, this can be a very serious insult to the digestive tract. There is loss of pancreatic exocrine function (causing steatorrhoea and malabsorption of protein, fats and fat-soluble vitamins), as well as the potential for small intestinal bacterial overgrowth (malabsorption of iron, folic acid and vitamin B₁₂).

**Ileal resection**

Ileal resection (p. 810) may give rise to vitamin B₁₂ deficiency and, rarely, to steatorrhoea and malabsorption of fat-soluble vitamins.

**Massive small bowel resection**

This may cause short bowel syndrome and intestinal failure, with impaired ability to absorb fluids, electrolytes and macronutrients adequately without parenteral support.

### An approach to assisted nutrition in hospital patients

Once the problems leading to under-nutrition have been recognised, it is important to make an individualised plan to address these issues specifically. In most cases, this means a decision to intervene to tackle and reverse nutritional difficulties. This may involve simply ensuring that adequate supplies of food are delivered and prepared regularly or that dentures fit properly, but may require an assessment of a patient’s ability to swallow or of the intestine’s ability to digest foods. This must include consideration of the potential for disruption of the normal physiology of absorption and digestion in the context of the patient’s medical and surgical history. Whenever possible, it is best to use the most physiological means of feeding, reserving more invasive interventions for when normal physiological mechanisms of swallowing and digestion are impaired or absent. Enteral feeding is preferred to parenteral, provided the intestine is accessible and functioning.

### Refeeding syndrome

In severely malnourished individuals, attempts at rapid correction of malnutrition switch the body from a reliance on fat to carbohydrate metabolism. Release of insulin is triggered, shifting potassium, phosphate and magnesium into cells (with water following the osmotic gradient) and causing potentially fatal shifts of fluids and electrolytes from the extracellular to the intracellular compartment. Rapid depletion of (already low) thiamin exacerbates the condition. Clinical features include nausea, vomiting, muscle weakness, seizures, respiratory depression, cardiac arrest and sudden death. The risks of refeeding are greatest in those who are most malnourished (especially chronic alcoholics), but even those who have gone without food for 5 days can be at risk and restitution of feeding should always be done slowly, with careful monitoring of serum potassium, phosphate and magnesium in the first 3–5 days.

### Oral nutritional supplements

Poor appetite, immobility, poor dentition or even being kept ‘nil by mouth’ for hospital procedures all contribute to weight loss. As a first step, patients should be encouraged and helped to eat an adequate amount of normal food. Where swallow and intestinal function remain intact, the simplest form of assisted nutrition is the use of oral nutritional supplements. Most branded products are nutritionally complete (fortified with the daily requirements of vitamins, minerals and trace elements). They most often come in the form of liquid drinks but various formulations and textures exist, including ‘shakes’ and ‘puddings’ with a thicker consistency. They are cost-effective and very useful for people who may require just a small number of additional calories each day to maintain or gain weight in the short or longer term. However, in spite of their nutritional value, small volume and range of flavours, many people find them unpalatable or difficult to tolerate.
Enteral feeding

Where swallowing or food ingestion is impaired but intestinal function remains intact, more invasive forms of assisted feeding may be necessary. Enteral tube feeding is usually the intervention of choice. In enteral feeding, nutrition is delivered to and absorbed by the functioning intestine. Delivery usually means bypassing the mouth and oesophagus (or sometimes the stomach and proximal small bowel) by means of a feeding tube (naso-enteral, gastrostomy or jejunostomy feeding). There are a number of theoretical advantages to enteral, as opposed to parenteral, feeding, which have achieved almost mythical status. These include:

- preservation of intestinal mucosal architecture, gut-associated lymphoid tissue, and hepatic and pulmonary immune function
- reduced levels of systemic inflammation and hyperglycaemia
- interference with pathogenicity of gut micro-organisms.

However, the areas in which advantage has been consistently proven are:

- fewer episodes of infection
- reduced cost
- earlier return to intestinal function
- reduced length of hospital stay.

Complications

The risks of enteral feeding are those related to tube insertion (Box 19.16) and diarrhoea (Box 19.17).

Route of access

Nasogastric tube feeding This is simple, readily available, comparatively low-cost and most suitable for short-term feeding (up to 4 weeks). Insertion of a nasogastric tube requires care and training (see Box 21.41, p. 805), as potentially serious complications can arise (Box 19.16). Patients with reduced conscious level may pull at tubes and displace them. This can be minimised in the short term by the use of a nasal ‘bridle’ device, which fixes the tube around the nasal septum. Although these devices are very effective, there is a risk of damage to the nasal septum (especially bleeding) if a patient persists in pulling forcibly on the tube.

Gastrostomy feeding Gastrostomy is a more invasive insertion technique with higher costs initially. It is most suitable for when longer-term feeding (more than 4 weeks) is required. Gastrostomies are less liable to displacement than nasogastric tubes and the presence of the gastrostomy in the stomach allows for fewer feed interruptions, meaning that more of the prescribed feeds can be administered. Tubes were placed at the time of open surgery until the 1980s, when an endoscopic, minimally invasive technique was developed. A variety of techniques for radiological insertion have also been introduced subsequently. Both endoscopic and radiological gastrostomy insertion involve inflicting the stomach, thus apposing it to the anterior abdominal wall. The stomach is then punctured percutaneously and a suitable tube placed (Fig. 19.10). Tubes vary in design but each has an internal retainer device (plastic ‘bumper’ or balloon) that sits snugly against the gastric mucosa, and an external retainer that limits movement. These retainers hold the gastric wall against the abdominal wall, effectively creating a controlled gastrocutaneous fistula that matures over 2–4 weeks. Radiological gastrostomy placement also utilises percutaneous ‘stay sutures’, which provide further temporary anchorage and assist in placement. There is no evidence to recommend one technique over another, although the radiological method has advantages in patients with cancers of the head and neck undergoing potentially curative therapy (less chance of tumour ‘seeding’) and in those with poor respiratory reserve (such as motor neuron disease) since there is no endoscope to compress the upper airways. Reported outcomes are broadly similar for both and the choice of technique should be based on indications and contraindications, operator experience and facilities available. Most important is rigorous patient assessment and selection prior to gastrostomy placement, which should be done by a multidisciplinary nutrition support team, and avoided when the procedure may be too hazardous or the benefits are outweighed by the risks (see Boxes 19.18 and 19.27 below).

Post-pyloric feeding In patients with a high risk of pulmonary aspiration or gastroparesis, it may be preferable to feed into the jejunum (via a nasojejunal tube, gastrostomy with jejunal extension or direct placement into jejunum by radiological, endoscopic or laparoscopic means).

Parenteral nutrition

This is usually reserved for clinical situations where the absorptive functioning of the intestine is severely impaired. In parenteral feeding, nutrition is delivered directly into a large-diameter systemic vein, completely bypassing the intestine and portal venous system. As well as being more invasive, more expensive and
Impair gastrointestinal function, such that oral or enteral feeding is not possible for at least 7 days.

**Intestinal failure (‘short bowel syndrome’)**

Intestinal failure (IF) is defined as a reduction in the function of the gut below the minimum necessary for the absorption of macronutrients and/or water and electrolytes such that intravenous supplementation is required to support health and/or growth. The term can be used only when there is both:

- a major reduction in absorptive capacity and
- an absolute need for intravenous fluid support.

IF can be further classified according to its onset, metabolic consequences and expected outcome.

- **Type 1 IF**: an acute-onset, usually self-limiting condition with few long-term sequelae. It is most often seen following abdominal surgery or in the context of critical illness. Intravenous support may be required for a few days to weeks.

Less physiological than the enteral route, parenteral nutrition is associated with many more complications (Box 19.19), mainly infective and metabolic (disturbances of electrolytes, hyperglycaemia). Strict adherence to aseptic practice in handling catheters and careful monitoring of clinical (pulse, blood pressure and temperature) and biochemical (urea, electrolytes, glucose and liver function tests) parameters are necessary to minimise risk to the patient (Box 19.20).

The parenteral route may be indicated for patients who are malnourished or at risk of becoming so, and who have an inadequate or unsafe oral intake and a poorly functioning or non-functioning or perforated intestine or an intestine that cannot be accessed by tube feeding. In practice, it is most often required in acutely ill patients with multi-organ failure or in severely under-nourished patients undergoing surgery. It may offer a benefit over oral or enteral feeding prior to surgery in those who are severely malnourished when other routes of feeding have been inadequate. Parenteral nutrition following surgery should be reserved for when enteral nutrition is not tolerated or feasible or where complications (especially sepsis) impair gastrointestinal function, such that oral or enteral feeding is not possible for at least 7 days.

**Fig. 19.10 Percutaneous endoscopic gastrostomy (PEG) placement.**

A. Finger pressure on the anterior abdominal wall is noted by the endoscopist. B. Following insertion of a cannula through the anterior abdominal wall into the stomach, a guidewire is threaded through the cannula and grasped by the endoscopic forceps or snare. C. The endoscope is withdrawn with the guidewire. The gastrostomy tube is then attached to the guidewire. D. The guidewire and tube are pulled back through the mouth, oesophagus and stomach to exit on the anterior abdominal wall, and the endoscope is repassed to confirm the site of placement of the retention device. The latter closely abuts the gastric mucosa; its position is maintained by an external fixation device (see inset). It is also possible to place PEG tubes using fluoroscopic guidance when endoscopy is difficult (radiologically inserted gastrostomy).
• Type 2 IF: far less common. The onset is also usually acute, following some intra-abdominal catastrophic event (ischaemia, volvulus, trauma or perioperative complication). Septic and metabolic problems are seen, along with complex nutritional issues. It requires multidisciplinary input (nursing, dietetic, medical, biochemical, surgical, radiological and microbiological) and support may be necessary for weeks to months.
• Type 3 IF: a chronic condition in which patients are metabolically stable but intravenous support is required over months to years. It may or may not be reversible.

Management
IF is a complex clinical problem with profound and wide-ranging physiological and psychological effects, which is best cared for by a dedicated multidisciplinary team. The majority of IF results from short bowel syndrome (Box 19.21), with chronic intestinal dysmotility and chronic intestinal pseudo-obstruction accounting for most of the remainder. The severity of the physiological upset correlates well with how much functioning intestine remains (rather than how much has been removed). Measurement of the remaining small bowel (from the duodeno-jejunal flexure) at the time of surgery is essential for planning future therapy (Box 19.22). The aims of treatment are to:
• provide nutrition, water and electrolytes to maintain health with normal body weight (and allow normal growth in affected children)
• utilise the enteral or oral routes as much as possible
• minimise the burden of complications of the underlying disease, as well as the IF and its treatment
• allow a good quality of life.

If the ileum and especially the ileum and colon remain intact, long-term nutritional support can usually be avoided. Unlike the jejunum, the ileum can adapt to increase absorption of water and electrolytes over time. The presence of the colon (part or wholly intact) further improves fluid absorption and can generate energy through production of short-chain fatty acids. It is therefore useful to classify patients with a short gut according to whether or not they have any residual colon.

Jejunum–colon patients
Those with an anastomosis between jejunum and residual colon (jejunum–colon patients) may look well in the days or initial weeks following the acute insult but develop protein-energy malnutrition and significant weight loss, becoming seriously under-nourished over weeks to months.

Stool volume is determined by oral intake, with higher intakes causing more diarrhoea and the potential for dehydration, sodium and magnesium depletion and acute renal failure. The absence of the ileum leads to deficiencies of vitamin B12 and fat-soluble vitamins. The absorption of various drugs, including thyroxine, digoxin and warfarin, can be reduced. Approximately 45% of patients will develop gallstones due to disruption of the enterohepatic circulation of bile acids, and 25% may develop calcium oxalate renal stones due to increased colonic absorption of oxalate (see Fig. 21.43, p. 810).

Jejunostomy patients
Patients left with a stoma (usually a jejunostomy) behave very differently, although stool volumes are again determined by oral intake. The jejunum is intrinsically highly permeable, and in the absence of the ileum and its net absorptive role, high losses of fluid, sodium and magnesium dominate the clinical picture from the outset. Dehydration, hypoponatraemia, hypomagnesaemia and acute renal failure are the most immediate problems but protein-energy malnutrition will also develop. The jejunum has no real potential for adaptation in terms of absorption, so it is essential to recognise and address the issues of dehydration and electrolyte disturbance early and not expect the problems to improve with time (Box 19.23).

19.23 Management of short bowel patients (and ‘high-output’ stoma)

Accurate charting of fluid intake and losses
• Vital: oral intake determines stool volume and should be restricted rather than encouraged

Dehydration and hyponatraemia
• Must first be corrected intravenously to restore circulating volume and reduce thirst
• Stool volume should be minimised and any ongoing fluid imbalance between oral intake and stool losses replenished intravenously

Measures to reduce stool volume losses
• Restrict oral fluid intake to ≤500 mL/24 hrs
• Give a further 1000 mL oral fluid as oral rehydration solution containing 90–120 mmol Na/L (St Mark’s solution or Glucodrate, Nestlé)
• Slow intestinal transit (to maximise opportunities for absorption): Loperamide, codeine phosphate
• Reduce volume of intestinal secretions: Gastric acid: omeprazole 20 mg/day orally Other secretions: octreotide 50–100 μg 3 times daily by subcutaneous injection

Measures to increase absorption
• Teduglutide (a recombinant glucagon-like peptide 2) significantly reduces requirements for intravenous fluid and nutritional support
Small bowel and multivisceral transplantation

Long-term intravenous nutritional support remains the mainstay of therapy for chronic IF but has its own morbidity and mortality. The 10-year survival for patients on long-term home parenteral nutrition is approximately 90%. The majority of deaths are due to the underlying disease process but 5–11% will die from direct complications of parenteral nutrition itself (especially catheter-related sepsis). A minority of patients with chronic IF, for whom the safe administration of parenteral nutrition has become difficult or impossible, may benefit from small bowel transplantation (Box 19.24). The first successful small bowel transplant was carried out in 1988. The introduction of tacrolimus allowed a satisfactory balance of immunosuppression, avoiding rejection while minimising sepsis. Since then, over 2000 transplants have been performed worldwide. Survival rates continue to improve, while minimising sepsis. Since then, over 2000 transplants have been performed worldwide. Survival rates continue to improve, although major complications are still frequent.

Further developments in treatment of intestinal failure

Teduglutide is a long-acting recombinant human GLP-2. It enhances intestinal absorption by:

- increasing intestinal blood flow to the intestine
- increasing portal blood flow away from the intestine
- slowing intestinal transit times
- reducing gastric acid secretion.

In patients with short bowel syndrome and IF, the increased intestinal absorptive function induced by teduglutide can significantly reduce the volumes of parenteral fluids and nutrition required, and may allow some patients to regain independence of parenteral support. Recognised side-effects include abdominal cramps and distension (seen in 50%), peristomal swelling, pain, nausea, vomiting and local injection site reactions. Since teduglutide stimulates proliferation of the intestinal epithelium, it should be avoided in those with a history of gastrointestinal malignancy in the past 5 years or a current malignancy. In those patients with a colon, a pre-treatment screening colonoscopy should be undertaken to detect and remove any polyps. Use of teduglutide is currently limited by high costs.

Artificial nutrition at the end of life

Rarely, assisted nutrition may not result in the expected outcomes of reversal of weight loss or improved quality and duration of life. It very seldom reverses other underlying health issues, although it may be used as a short term ‘bridge’ to help through a patient through a particular crisis.

Such scenarios may present when someone is approaching the end of life, or in the face of weight loss due to advanced
Micronutrients, minerals and their diseases

Vitamins

Vitamins are organic substances with key roles in certain metabolic pathways, and are categorised into those that are fat-soluble (vitamins A, D, E and K) and those that are water-soluble (vitamins of the B complex group and vitamin C).

*Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten.

Nutrition and dementia

Weight loss is seen commonly in people with dementia, and nutritional and eating problems are a significant source of concern for those caring for them. It is appropriate to:

- screen for malnutrition (e.g. MUST, see above)
- assess specific eating difficulties (e.g. Edinburgh Feeding Evaluation in Dementia questionnaire)
- monitor and document body weight
- encourage adequate intake of food
- use oral nutritional supplements.

However, the evidence that artificial nutritional support beyond oral supplementation improves overall functioning or prolongs life in dementia is absent or weak. There may be specific circumstances where a trial of such feeding can be justified (see Box 19.27). Success is more likely in those with mild to moderate dementia, when a temporary and reversible crisis has been precipitated by some acute event. It is important to remember that there is strong evidence to avoid tube feeding in those with advanced dementia because this improves neither the quality nor the duration of life (Fig. 19.11).

Micronutrients, minerals and their diseases

Vitamins are organic substances with key roles in certain metabolic pathways, and are categorised into those that are fat-soluble (vitamins A, D, E and K) and those that are water-soluble (vitamins of the B complex group and vitamin C).

Recommended daily intakes of micronutrients (Box 19.28) vary between countries and the nomenclature has become potentially confusing. In the UK, the ‘reference nutrient intake’ (RNI) has been calculated as the mean plus two standard deviations (SD) of daily intake in the population, which therefore describes normal intake for 97.5% of the population. The lower reference intake (INT) has been calculated as the mean minus two standard deviations of daily intake in the population, which therefore describes normal intake for 2.5% of the population. In selected cases, a decision not to intervene may be appropriate. An intervention that merely prolongs life without preserving or adding to its quality is seldom justified, particularly if the intervention is not without risk itself. Such decisions are not taken lightly and careful scrutiny of each case is necessary. There should be a thoughtful and sensitive discussion explaining what artificial nutrition can and cannot achieve involving the multidisciplinary team looking after the patient as well as next of kin and, in some cases, legal representatives (Box 19.27).
19.29 Nutrition in pregnancy and lactation

- **Energy requirements**: increased in both mother and fetus but can be met through reduced maternal energy expenditure.
- **Micronutrient requirements**: adaptive mechanisms ensure increased uptake of minerals in pregnancy, but extra increments of some are required during lactation (see Box 19.32). Additional increments of some vitamins are recommended during pregnancy and lactation:
  - **Vitamin A**: for growth and maintenance of the fetus, and to provide some reserve (important in some countries to prevent blindness associated with vitamin A deficiency). Teratogenic in excessive amounts.
  - **Vitamin D**: to ensure bone and dental development in the infant. Higher incidences of hypocalcaemia, hypoparathyroidism and defective dental enamel have been seen in infants of women not taking vitamin D supplements at >50° latitude.
  - **Folate**: taken pre-conceptually and during the first trimester, reduces the incidence of neural tube defects by 70%.
  - **Vitamin B12**: in lactation only.
  - **Thiamin**: to meet increased fetal energy demands.
  - **Riboflavin**: to meet extra demands.
  - **Niacin**: in lactation only.
  - **Vitamin C**: for the last trimester to maintain maternal stores as fetal demands increase.
  - **Iodine**: in countries with high consumption of staple foods (e.g. brassicas, maize, bamboo shoots) that contain goitrogens (thiocyanates or perchlorates) that interfere with iodine uptake, supplements prevent infants being born with cretinism.

19.30 Vitamin deficiency in old age

- **Requirements**: although requirements for energy fall with age, those for micronutrients do not. If dietary intake falls, a vitamin-rich diet is required to compensate.
- **Vitamin D**: levels are commonly low due to reduced dietary intake, decreased sun exposure and less efficient skin conversion. This leads to bone loss and fractures. Supplements should be given to those at risk of falls in institutional care – the group at highest risk.
- **Vitamin B12**: an increased rate of bone loss in older people is adaptive mechanisms ensure.
- **Vitamin B12** deficiency: a causal relationship with dementia has not been identified, but it does produce neuropsychiatric effects and should be checked in all those with declining cognitive function.

Nutrient intake (LRNI) is the mean minus 2 SD, below which would be considered deficient in most of the population. These dietary reference values (DRV) have superseded the terms RDI (recommended daily intake) and RDA (recommended daily amount). Other countries use different terminology. Additional amounts of some micronutrients may be required in pregnancy and lactation (Box 19.29).

Vitamin deficiency diseases are most prevalent in developing countries but still occur in developed countries. Older people (Box 19.30) and alcoholics are at risk of deficiencies in B vitamins and in vitamins D and C. Nutritional deficiencies in pregnancy can affect either the mother or the developing fetus, and extra increments of vitamins are recommended in the UK (see Box 19.29). Darker-skinned individuals living at higher latitude, and those who cover up or do not go outside are at increased risk of vitamin D deficiency due to inadequate sunlight exposure. Dietary supplements are recommended for these ‘at-risk’ groups. Some nutrient deficiencies are induced by diseases or drugs. Deficiencies of fat-soluble vitamins are seen in conditions of fat malabsorption (Box 19.31).

19.31 Gastrointestinal disorders that may be associated with malabsorption of fat-soluble vitamins

- Biliary obstruction
- Pancreatic exocrine insufficiency
- Coeliac disease
- Ileal inflammation or resection

Some vitamins also have pharmacological actions when given at supraphysiological doses, such as the use of vitamin A for acne (p. 1242). Taking vitamin supplements is fashionable in many countries, although there is no evidence of benefit. Toxic effects are most serious with high dosages of vitamins A, B6 and D.

Investigation of suspected vitamin deficiency or excess may involve biochemical assessment of body stores (Box 19.32). Measurements in blood should be interpreted carefully, however, in conjunction with the clinical presentation.

Fat-soluble vitamins

**Vitamin A (retinol)**

Pre-formed retinol is found only in foods of animal origin. Vitamin A can also be derived from carotenes, which are present in green and coloured vegetables and some fruits. Carotenes provide most of the total vitamin A in the UK and constitute the only supply in vegans. Retinol is converted to several other important molecules:

- **11-cis-retinaldehyde** is part of the photoreceptor complex in rods of the retina.
- **Retinoic acid** induces differentiation of epithelial cells by binding to specific nuclear receptors, which induce responsive genes. In vitamin A deficiency, mucus-secreting cells are replaced by keratin-producing cells.
- **Retinoids** are necessary for normal growth, fetal development, fertility, haematopoiesis and immune function.

Globally, the most important consequence of vitamin A deficiency is irreversible blindness in young children. Asia is most notably affected and the problem is being addressed through widespread vitamin A supplementation programmes. Adults are not usually at risk because liver stores can supply vitamin A when foods containing vitamin A are unavailable.

Early deficiency causes impaired adaptation to the dark (night blindness). Keratinisation of the cornea (xerophthalmia) gives rise to characteristic Bitot’s spots and progresses to keratomalacia, with corneal ulceration, scarring and irreversible blindness (Fig. 19.12). In countries where vitamin A deficiency is endemic, pregnant women should be advised to eat dark green, leafy vegetables and yellow fruits (to build up stores of retinol in the fetal liver), and infants should be fed the same. The WHO is according high priority to prevention in communities where xerophthalmia occurs, giving single prophylactic oral doses of 60 mg retinyl palmitate (providing 200,000 U retinol) to pre-school children. This also reduces mortality from gastroenteritis and respiratory infections.

Repeated moderate or high doses of retinol can cause liver damage, hyperostosis and teratogenicity. Women in countries where deficiency is not endemic are therefore advised not to take vitamin A supplements in pregnancy. Retinol intake may also be restricted in those at risk of osteoporosis. Acute overdose leads to nausea and headache, increased intracranial pressure and skin desquamation. Excessive intake of carotene can cause pigmentation of the skin (hypercarotenosis); this gradually fades when intake is reduced.

**Vitamin D**

The natural form of vitamin D, cholecalciferol or vitamin D₃, is formed in the skin by the action of ultraviolet (UV) light on 7-dehydrocholesterol, a metabolite of cholesterol. Few foods contain vitamin D naturally and skin exposure to sunlight is the main source. Moving away from the equator, the intensity of UV light decreases, so that at a latitude above 50° (including northern Europe) vitamin D is not synthesised in winter, and even above 30° there is seasonal variation. The body store accumulated during the summer is consumed during the winter. Vitamin D is converted in the liver to 25-hydroxyvitamin D (25(OH)D), which is further hydroxylated in the kidneys to 1,25-dihydroxyvitamin D (1,25(OH)₂D), the active form of the vitamin (see Fig. 24.61, p. 1051). This 1,25(OH)₂D activates specific intracellular receptors that influence calcium metabolism, bone mineralisation and tissue differentiation. The synthetic form, ergocalciferol or vitamin D₂, is considered to be less potent than endogenous D₃.

Recommended dietary intakes aim to improve musculoskeletal health, preventing rickets and osteomalacia, enhancing muscle strength and reducing the risks of falls in the elderly. Adequate levels of vitamin D may also be important in non-musculoskeletal conditions and may improve immune function (p. 1309). Margarines are fortified with vitamin D in the UK, and milk is fortified in some parts of Europe and in North America. However, the combination of low dietary intake and limited sunlight exposure in the UK has led to recommendations that everyone over the age of 5 should take 10 μg of vitamin D daily. The individuals at highest risk of vitamin D deficiency are those who have limited exposure to sunshine. People who are confined indoors, those who habitually cover up their skin when outdoors and those with darker skins should take 10 μg of vitamin D per day all year round. Other groups may require such supplementation only in the winter months of October to March.

The effects of vitamin D deficiency (calcium deficiency, rickets and osteomalacia) are described on page 1049. An analogue of vitamin D (calcipotriol) is used for treatment of skin conditions such as psoriasis. Excessive doses of cholecalciferol, ergocalciferol or the hydroxylated metabolites cause hypercalcaemia (p. 661).

**Vitamin E**

There are eight related fat-soluble substances with vitamin E activity. The most important dietary form is α-tocopherol. Vitamin E has many direct metabolic actions:

- It prevents oxidation of polyunsaturated fatty acids in cell membranes by free radicals.
- It helps maintain cell membrane structure.
- It affects DNA synthesis and cell signalling.
- It is involved in the anti-inflammatory and immune systems.
Human deficiency is rare and has been described only in premature infants and in malabsorption. It can cause a mild haemolytic anaemia, ataxia and visual scotomas. Vitamin E intakes of up to 3200 mg/day (1000-fold greater than recommended intakes) are considered safe. Diets rich in vitamin E are consumed in countries with lower rates of coronary heart disease, although randomised controlled trials have not demonstrated cardioprotective effects of vitamin E or other antioxidants.

**Vitamin K**

Vitamin K is supplied in the diet mainly as vitamin K₁ (phylloquinone) in the UK, or as vitamin K₂ (menaquinone) from fermented products in parts of Asia. Vitamin K₂ is also synthesised by bacteria in the colon. Vitamin K is a co-factor for carboxylation reactions: in particular, the production of γ-carboxyglutamate (gla). Gla residues are found in four of the coagulation factor proteins (II, VII, IX and X; p. 918), conferring their capacity to bind to phospholipid surfaces in the presence of calcium. Other important gla proteins are osteocalcin and matrix gla protein, which are important in bone mineralisation.

Vitamin K deficiency leads to delayed coagulation and bleeding. In obstructive jaundice, dietary vitamin K is not absorbed and it is essential to administer the vitamin in parenteral form before surgery. Warfarin and related anticoagulants (p. 939) act by antagonising vitamin K. Vitamin K is given routinely to newborn babies to prevent haemorrhagic disease. Symptoms of excess have been reported only in infants, with synthetic preparations linked to haemolysis and liver damage.

### Water-soluble vitamins

**Thiamin (vitamin B₁)**

Thiamin is widely distributed in foods of both vegetable and animal origin. Thiamin pyrophosphate (TPP) is a co-factor for enzyme reactions involved in the metabolism of macronutrients (carbohydrate, fat and alcohol), including:

- decarboxylation of pyruvate to acetyl-co-enzyme A, which bridges between glycolysis and the tricarboxylic acid (Krebs) cycle
- transketolase activity in the hexose monophosphate shunt pathway
- decarboxylation of α-ketoglutarate to succinate in the Krebs cycle.

In thiamin deficiency, cells cannot metabolise glucose aerobically to generate energy as ATP. Neuronal cells are most vulnerable because they depend almost exclusively on glucose for energy requirements. Impaired glucose oxidation also causes an accumulation of pyruvic and lactic acids, which produce vasodilatation and increased cardiac output.

**Deficiency – beri-beri**

In the developed world, thiamin deficiency is mainly encountered in chronic alcoholics. Poor diet, impaired absorption, storage and phosphorylation of thiamin in the liver, and the increased requirements for thiamin to metabolise ethanol all contribute. In the developing world, deficiency usually arises as a consequence of a diet based on polished rice. The body has very limited stores of thiamin, so deficiency is manifest after only 1 month on a thiamin-free diet. There are two forms of the disease in adults:

- **Dry (or neurological) beri-beri** manifests with chronic peripheral neuropathy and with wrist and/or foot drop, and may cause Korsakoff’s psychosis and Wernicke’s encephalopathy (p. 1195).
- **Wet (or cardiac) beri-beri** causes generalised oedema due to biventricular heart failure with pulmonary congestion.

In dry beri-beri, response to thiamin administration is not uniformly good. Multivitamin therapy seems to produce some improvement, however, suggesting that other vitamin deficiencies may be involved. Wernicke’s encephalopathy and wet beri-beri should be treated without delay with intravenous vitamin B and C mixture (Pabrinex, p. 1195). Korsakoff’s psychosis is irreversible and does not respond to thiamin treatment.

**Riboflavin (vitamin B₂)**

Riboflavin is required for the flavin co-factors involved in oxidation-reduction reactions. It is widely distributed in animal and vegetable foods. Levels are low in staple cereals but germination increases its content. It is destroyed under alkaline conditions by heat and by exposure to sunlight. Deficiency is rare in developed countries. It mainly affects the tongue and lips and manifests as glossitis, angular stomatitis and cheilosis. The genitals may be involved, as well as the skin areas rich in sebaceous glands, causing nasolabial or facial dyssebacea. Rapid recovery usually follows administration of riboflavin 10 mg daily by mouth.

**Niacin (vitamin B₃)**

Niacin encompasses nicotinic acid and nicotinamide. Nicotinamide is an essential part of the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which play a key role as hydrogen acceptors and donors for many enzymes. Niacin can be synthesised in the body in limited amounts from the amino acid tryptophan.

**Deficiency – pellagra**

Pellagra was formerly endemic among poor people who subsisted chiefly on maize, which contains niacytin, a form of niacin that the body is unable to utilise. Pellagra can develop in only 8 weeks in individuals eating diets that are very deficient in niacin and tryptophan. It remains a problem in parts of Africa, and is occasionally seen in alcoholics and in patients with chronic small intestinal disease in developed countries. Pellagra can occur in Hartnup’s disease, a genetic disorder characterised by impaired absorption of several amino acids, including tryptophan. It is also seen occasionally in carcinoid syndrome (p. 678), when tryptophan is consumed in the excessive production of 5-hydroxytryptamine (5-HT, serotonin). Pellagra has been called the disease of the three Ds:

- **Dermatitis.** Characteristically, there is erythema resembling severe sunburn, appearing symmetrically over the parts of the body exposed to sunlight, particularly the limbs and especially on the neck but not the face (Casal’s necklace, Fig. 19.13). The skin lesions may progress to vesiculation, cracking, exudation and secondary infection.
- **Diarhoea.** This is often associated with anorexia, nausea, glossitis and dysphagia, reflecting the presence of a non-infective inflammation that extends throughout the gastrointestinal tract.
- **Dementia.** In severe deficiency, delirium occurs acutely and dementia develops in chronic cases.

Treatment is with nicotinamide, given in a dose of 100 mg 3 times daily orally or parenterally. The response is usually rapid. Within 24 hours the erythema diminishes, the diarrhoea ceases and a striking improvement occurs in the patient’s mental state.
Enzymes involved in the metabolism of amino acids. Vitamin B6 (pyridoxine, pyridoxal and pyridoxamine) are different forms of vitamin B6 that undergo phosphorylation to produce pyridoxal 5-phosphate (PLP). PLP is the co-factor for a large number of enzyme reactions. Folates exist in many forms. The main circulating form is 5-methyltetrahydrofolate. The natural forms are prone to oxidation. Folate (folic acid) is the stable synthetic form. Folate works as a methyl donor for cellular methylation and protein synthesis. It is directly involved in DNA and RNA synthesis, and requirements increase during embryonic development.

Folate deficiency may cause three major birth defects (spina bifida, anencephaly and encephalocele) resulting from imperfect closure of the neural tube, which takes place 3–4 weeks after conception. The UK Department of Health advises that women who have experienced a pregnancy affected by a neural tube defect should take 5 mg of folate acid daily from before conception and throughout the first trimester; this reduces the incidence of these defects by 70%. All women planning a pregnancy are advised to include good sources of folate in their diet, and to take folate supplements throughout the first trimester. Liver is the richest source of folate but an alternative source (e.g. leafy vegetables) is advised in early pregnancy because of the high vitamin A content of liver (p. 712). Folate deficiency has also been associated with heart disease, dementia and cancer. There is mandatory fortification of flour with folic acid in the USA and voluntary fortification of many foods across Europe. There are now concerns that this may contribute to the increased incidence of colon cancer through promotion of the growth of polyps.

**Hydroxycobalamin (vitamin B12)**

Vitamin B12 is a co-factor in folate co-enzyme recycling and nerve myelination. Vitamin B12 and folic acid are particularly important in DNA synthesis in red blood cells (p. 943). The haematological disorders (macrocytic or megaloblastic anaemias) caused by their deficiency are discussed on pages 943–945. Vitamin B12 deficiency is also associated with neurological disease (see Box 23.33, p. 944).

**Neurological consequences of vitamin B12 deficiency**

In older people and chronic alcoholics, vitamin B12 deficiency arises from insufficient intake and/or from malabsorption. Several drugs, including neomycin, can render vitamin B12 inactive. Adequate intake of folate maintains erythropoiesis and there is a concern that fortification of foods with folate may mask underlying vitamin B12 deficiency. In severe deficiency there is insidious, diffuse and uneven demyelination. It may be clinically manifest as peripheral neuropathy or spinal cord degeneration affecting both posterior and lateral columns ("subacute combined degeneration of the spinal cord"; p. 1138), or there may be cerebral manifestations (resembling dementia) or optic atrophy. Vitamin B12 therapy improves symptoms in most cases.

**Vitamin C (ascorbic acid)**

Ascorbic acid is the most active reducing agent in the aqueous phase of living tissues and is involved in intracellular electron transfer. It takes part in the hydroxylation of proline and lysine in protocollagen to hydroxyproline and hydroxylysine in mature collagen. It is very easily destroyed by heat, increased pH and light, and is very soluble in water; hence many traditional cooking methods reduce or eliminate it. Claims that high-dose vitamin C improves immune function (including resistance to the common cold) and cholesterol turnover remain unsubstantiated.

**Deficiency – scurvy**

Vitamin C deficiency causes defective formation of collagen with impaired healing of wounds, capillary haemorrhage and reduced platelet adhesiveness (normal platelets are rich in ascorbate) (Fig. 19.14). Precipitants and clinical features of scurvy are shown...
inadequate dietary intake of minerals or excessive loss from the body. Toxic effects have also been observed from self-medication and disordered absorption or excretion. Examples of clinical toxicity include excess of iron (haemochromatosis or haemosiderosis), fluoride (fluorosis; p. 149), copper (Wilson’s disease) and selenium (selenosis, seen in parts of China). For most minerals, the available biochemical markers do not accurately reflect dietary intake and dietary assessment is required.

Calcium and phosphorus

Calcium is the most abundant cation in the body and powerful homeostatic mechanisms control circulating ionised calcium levels (pp. 661 and 1050). The WHO’s dietary guidelines for calcium differ between countries, with higher intakes usually recommended in places with higher fracture prevalence. Between 20% and 30% of calcium in the diet is absorbed, depending on vitamin D status and food source. Calcium requirements depend on phosphorus intakes, with an optimum molar ratio (Ca:P) of 1:1. Excessive phosphorus intakes (e.g. 1–1.5 g/day) with a Ca:P of 1:3 have been shown to cause hypocalcaemia and secondary hyperparathyroidism (p. 662).

Calcium absorption may be impaired in vitamin D deficiency (pp. 661 and 1050) and in malabsorption secondary to small intestinal disease. Calcium deficiency causes impaired bone mineralisation and can lead to osteomalacia in adults. The potential benefits of high calcium intake in osteoporosis are discussed on page 1048. Too much calcium can lead to constipation, and toxicity has been observed in ‘milk-alkali syndrome’ (p. 662).

Deficiency may be impaired in vitamin D deficiency and in malabsorption secondary to small intestinal disease. Calcium deficiency causes impaired bone mineralisation and can lead to osteomalacia in adults. The potential benefits of high calcium intake in osteoporosis are discussed on page 1048. Too much calcium can lead to constipation, and toxicity has been observed in ‘milk-alkali syndrome’ (p. 662).

Other dietary organic compounds

There are a number of non-essential organic compounds with purported health benefits, such as reducing risk of heart disease or cancer. Groups of compounds such as the flavonoids and phytoestrogens show bioactivity through their respective antioxidant and oestrogenic or anti-oestrogenic activities. Flavonoids (of which there are a number of different classes of compound) are found in fruit and vegetables, tea and wine; phytoestrogens are found in soy products (with higher intakes in parts of Asia compared to Europe and the USA) and pulses. Caffeine from tea and coffee and carbonated beverages affects the nervous system and can improve mental performance in the short term, with adverse effects seen at higher intakes. Intake of non-carbolic organic acids (which are not metabolised to carbon dioxide), e.g. oxalates, may be restricted in individuals prone to kidney stones.

Inorganic micronutrients

A number of inorganic elements are essential dietary constituents for humans (Box 19.34). Deficiency is seen when there is inadequate dietary intake of minerals or excessive loss from the body. Toxic effects have also been observed from self-medication and disordered absorption or excretion. Examples of clinical toxicity include excess of iron (haemochromatosis or haemosiderosis), fluoride (fluorosis; p. 149), copper (Wilson’s disease) and selenium (selenosis, seen in parts of China). For most minerals, the available biochemical markers do not accurately reflect dietary intake and dietary assessment is required.

Calcium and phosphorus

Calcium is the most abundant cation in the body and powerful homeostatic mechanisms control circulating ionised calcium levels (pp. 661 and 1050). The WHO’s dietary guidelines for calcium differ between countries, with higher intakes usually recommended in places with higher fracture prevalence. Between 20% and 30% of calcium in the diet is absorbed, depending on vitamin D status and food source. Calcium requirements depend on phosphorus intakes, with an optimum molar ratio (Ca:P) of 1:1. Excessive phosphorus intakes (e.g. 1–1.5 g/day) with a Ca:P of 1:3 have been shown to cause hypocalcaemia and secondary hyperparathyroidism (p. 662).

Calcium absorption may be impaired in vitamin D deficiency (pp. 661 and 1050) and in malabsorption secondary to small intestinal disease. Calcium deficiency causes impaired bone mineralisation and can lead to osteomalacia in adults. The potential benefits of high calcium intake in osteoporosis are discussed on page 1048. Too much calcium can lead to constipation, and toxicity has been observed in ‘milk-alkali syndrome’ (p. 662).

Deficiency of calcium in infants fed exclusively on boiled milk.

Dietary deficiency

- Lack of dietary fruit and vegetables for >2 months
- Infants fed exclusively on boiled milk

Clinical features

- Swollen gums that bleed easily
- Perifollicular and petechial haemorrhages
- Ecchymoses
- Haemarthrosis
- Gastrointestinal bleeding
- Anaemia
- Poor wound healing

in Box 19.33. A dose of 250 mg vitamin C 3 times daily by mouth should saturate the tissues quickly. The deficiencies of the patient’s diet also need to be corrected and other vitamin supplements given if necessary. Daily intakes of more than 1 g/day have been reported to cause diarrhoea and the formation of renal oxalate stones.

Other dietary organic compounds

There are a number of non-essential organic compounds with purported health benefits, such as reducing risk of heart disease or cancer. Groups of compounds such as the flavonoids and phytoestrogens show bioactivity through their respective antioxidant and oestrogenic or anti-oestrogenic activities. Flavonoids (of which there are a number of different classes of compound) are found in fruit and vegetables, tea and wine; phytoestrogens are found in soy products (with higher intakes in parts of Asia compared to Europe and the USA) and pulses. Caffeine from tea and coffee and carbonated beverages affects the nervous system and can improve mental performance in the short term, with adverse effects seen at higher intakes. Intake of non-carbolic organic acids (which are not metabolised to carbon dioxide), e.g. oxalates, may be restricted in individuals prone to kidney stones.

Inorganic micronutrients

A number of inorganic elements are essential dietary constituents for humans (Box 19.34). Deficiency is seen when there is
poorly absorbed but makes the greater contribution to overall intake, compared to the well-absorbed haem iron from animal products. Fruits and vegetables containing vitamin C enhance iron absorption, while the tannins in tea reduce it. Dietary calcium reduces iron uptake from the same meal, which may precipitate iron deficiency in those with borderline iron stores. There is no physiological mechanism for excretion of iron, so homeostasis depends on the regulation of iron absorption (see Fig. 23.18, p. 942). This is regulated at the level of duodenal enterocytes by hepcidin (a peptide secreted by hepatocytes in the duodenum). The expression of hepcidin is suppressed when body iron is low, or by provision of iodised salt for cooking.

Iodine is required for synthesis of thyroid hormones (p. 634). It is present in sea fish, seaweed and most plant foods grown near the sea. The amount of iodine in soil and water influences the iodine content of most foods. Iodine is lacking in the highest mountainous areas of the world (e.g. the Alps and the Himalayas) and in the soil of frequently flooded plains (e.g. Bangladesh). About a billion people in the world are estimated to have an inadequate iodine intake and hence are at risk of iodine deficiency disorder. Goitre is the most common manifestation, affecting about 200 million people (p. 648).

In those areas where most women have endemic goitre, 1% or more of babies are born with cretinism (characterised by mental and physical retardation). There is a higher than usual prevalence of deafness, slowed reflexes and poor learning in the remaining population. The best way of preventing neonatal cretinism is to ensure adequate levels of iodine during pregnancy. This can be achieved by intramuscular injections with 1–2 mL of iodised poppy seed oil (475–950 mg iodine) to women of child-bearing age every 3–5 years, by administration of iodised oil orally at 6-monthly or yearly intervals to adults and children, or by provision of iodised salt for cooking.

**Zinc**

Zinc is present in most foods of vegetable and animal origin. It is an essential component of many enzymes, including carbonic anhydrase, alcohol dehydrogenase and alkaline phosphatase. Acute zinc deficiency has been reported in patients receiving prolonged zinc-free parenteral nutrition and causes diarrhoea, mental apathy, a moist, eczematoid dermatitis, especially around the mouth, and loss of hair. Chronic zinc deficiency occurs in dietary deficiency, malabsorption syndromes, alcoholism and its associated hepatic cirrhosis. It causes the clinical features seen in the very rare congenital disorder known as acrodermatitis enteropathica (growth retardation, hair loss and chronic diarrhoea). Zinc deficiency is thought to be responsible for one-third of the world’s population not reaching their optimal height. In the Middle East, chronic deficiency has been associated with dwarfism and hypogonadism. In starvation, zinc deficiency causes thymic atrophy; zinc supplements may accelerate the healing of skin lesions, promote general well-being, improve appetite and reduce the morbidity associated with the under-nourished state, and lower the mortality associated with diarrhoea and pneumonia in children.
Selenium

The family of seleno-enzymes includes glutathione peroxidase, which helps prevent free radical damage to cells, and monodeiodinase, which converts thyroxine to triiodothyronine (p. 634). North American soil has a higher selenium content than European and Asian soil, and the decreasing reliance of Europe on imported American food in recent decades has resulted in a decline in dietary selenium intake.

Selenium deficiency can cause hypothyroidism, cardiomyopathy in children (Keshan’s disease) and myopathy in adults. Excess selenium can cause heart disease.

Fluoride

Fluoride helps prevent dental caries because it increases the resistance of the enamel to acid attack. It is a component of bone mineral and some studies have shown anti-fracture effects at low doses, but excessive intakes may compromise bone structure.

If the local water supply contains more than 1 part per million (ppm) of fluoride, the incidence of dental caries is low. Soft waters usually contain no fluoride, while very hard waters may contain over 10 ppm. The benefit of fluoride is greatest when it is taken before the permanent teeth erupt, while their enamel is being laid down. The addition of traces of fluoride (at 1 ppm) to public water supplies is now a widespread practice. Chronic fluoride poisoning is occasionally seen where the water supply contains >10 ppm fluoride. It can also occur in workers handling cryolite (aluminium sodium fluoride), used in smelting aluminium. Fluoride poisoning is described on page 149. Pitting of teeth is a result of too much fluoride as a child.

Sodium, potassium and magnesium

Western diets are high in sodium due to the sodium chloride (salt) that is added to processed food. In the UK, it is suggested that daily salt intakes are kept well below 6 g. The roles of sodium, potassium and magnesium, along with the disease states associated with abnormal intakes or disordered metabolism, are discussed in Chapter 14.

Other essential inorganic nutrients

These include chloride (a counter-ion to sodium and potassium), cobalt (required for vitamin B_{12}), sulphur (a constituent of methionine and cysteine), manganese (needed for or activates many enzymes) and chromium (necessary for insulin action). Deficiency of chromium presents as hyperglycaemia and has been reported in adults as a rare complication of prolonged parenteral nutrition.

Copper metabolism is abnormal in Wilson’s disease (p. 896). Deficiency occasionally occurs but only in young children, causing microcytic hypochromic anaemia, neutropenia, retarded growth, skeletal rarefaction and dermatosis.

Clinical examination of the patient with diabetes

6 Head
   Xanthelasma
   Cranial nerve palsy/eye movements/ptosis

5 Neck
   Carotid pulse
   Bruits
   Thyroid enlargement

4 Axillae
   Acanthosis nigricans in insulin resistance

3 Blood pressure

2 Skin
   Bullae
   Pigmentation
   Granuloma annulare
   Vitiligo

1 Hands
   (see opposite)
   ‘Prayer sign’

7 Eyes (see opposite)
   Visual acuity
   Cataract/lens opacity
   Fundoscopy

8 Insulin injection sites
   (see opposite)

9 Abdomen
   Hepatomegaly
   (fatty infiltration of liver)

10 Legs
   Muscle-wasting
   Sensory abnormality
   Hair loss
   Tendon reflexes

11 Feet (see opposite)
   Inspection
   Peripheral pulses
   Sensation
   Neuropathic foot ulcer
   Charcot neuroarthropathy

Observation
   • Weight loss in insulin deficiency
   • Obesity in type 2 diabetes
   • Mucosal candidiasis
   • Dehydration– dry mouth, ↓ tissue turgor
   • Air hunger– Kussmaul breathing in ketoacidosis

Clinical examination of the patient with diabetes

Diabetes can affect every system in the body. In routine clinical practice, examination of the patient with diabetes is focused on hands, blood pressure, axillae, neck, eyes, insulin injection sites and feet.

7 Examination of the hands

Several abnormalities are more common in diabetes:
- Limited joint mobility (‘cheiroarthropathy’) causes painless stiffness. The inability to extend (to 180°) the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the ‘prayer sign’
- Dupuytren’s contracture (p. 1059) causes nodules or thickening of the skin and knuckle pads
- Carpal tunnel syndrome (p. 1139) presents with wrist pain radiating into the hand
- Trigger finger (flexor tenosynovitis) may be present
- Muscle-wasting/sensory changes may be present in peripheral sensorimotor neuropathy, although this is more common in the lower limbs

8 Insulin injection sites

Main areas used
- Anterior abdominal wall
- Upper thighs/buttocks
- Upper outer arms

Inspection
- Bruising
- Subcutaneous fat deposition (lipohypertrophy)
- Subcutaneous fat loss (lipoatrophy; associated with injection of unpurified animal insulins – now rare)
- Erythema, infection (rare)

11 Examination of the feet

Inspection
- Look for evidence of callus formation on weight-bearing areas, clawing of the toes (in neuropathy), loss of the plantar arch, discoloration of the skin (ischaemia), localised infection and ulcers
- Deformity may be present, especially in Charcot neuroarthropathy
- Fungal infection may affect skin between toes, and nails

Circulation
- Peripheral pulses, skin temperature and capillary refill may be abnormal

Sensation
- This is abnormal in stocking distribution in typical peripheral sensorimotor neuropathy
- Testing light touch with monofilaments is sufficient for risk assessment; test other sensation modalities (vibration, pain, proprioception) only when neuropathy is being evaluated

Reflexes
- Ankle reflexes are lost in typical sensorimotor neuropathy
- Test plantar and ankle reflexes

Monofilaments. The monofilament is applied gently until slightly deformed at five points on each foot. Callus should be avoided as sensation is reduced. If the patient feels fewer than 8 out of 10 touches, the risk of foot ulceration is increased 5–10-fold.
Diabetes mellitus is a clinical syndrome characterised by an increase in plasma blood glucose (hyperglycaemia). It has many causes (see Box 20.9), most commonly type 1 or type 2 diabetes. Type 1 diabetes is generally considered to result from autoimmune destruction of insulin-producing cells (β cells) in the pancreas, leading to marked insulin deficiency, whereas type 2 diabetes is characterised by reduced sensitivity to the action of insulin and an inability to produce sufficient insulin to overcome this ‘insulin resistance’. Hyperglycaemia causes both acute and long-term problems. Acutely, high glucose and lack of insulin can result in marked symptoms, metabolic decompensation and hospitalisation. Chronic hyperglycaemia is responsible for diabetes-specific ‘microvascular’ complications affecting the eyes (retinopathy), kidneys (nephropathy) and feet (neuropathy).

There is a continuous distribution of blood glucose in the population, with no clear division between people with normal values and those with abnormal ones. The diagnostic criteria for diabetes (a fasting plasma glucose of \(\geq 7.0 \text{ mmol/L (126 mg/dL)}\) or glucose 2 hours after an oral glucose challenge of \(\geq 11.1 \text{ mmol/L (200 mg/dL)}\); p. 726) have been selected to identify a degree of hyperglycaemia that, if untreated, carries a significant risk of microvascular disease, and in particular diabetic retinopathy. Less severe hyperglycaemia is called ‘impaired glucose tolerance’. This is not associated with a substantial risk of microvascular disease, but is connected with an increased risk of large-vessel disease (e.g. atheroma leading to myocardial infarction) and with a greater risk of developing diabetes in future.

The incidence of diabetes is rising. Globally, it is estimated that 415 million people had diabetes in 2015 (10% of the world adult population), and this figure is expected to reach 642 million by 2040. This global pandemic principally involves type 2 diabetes; prevalence varies considerably around the world (Fig. 20.1), being associated with differences in genetic factors, as well as environmental ones such as greater longevity, obesity, unsatisfactory diet, sedentary lifestyle, increasing urbanisation and economic development. A pronounced rise in the prevalence of type 2 diabetes occurs in migrant populations to industrialised countries, as in Asian and Afro-Caribbean immigrants to the UK or USA. Type 2 diabetes is now seen in children and adolescents, particularly in some ethnic groups such as Hispanics, non-Hispanic blacks and Asian Indians.

The incidence of type 1 diabetes is also increasing: between 1960 and 1996, 3% more children were diagnosed worldwide each year. It is generally more common in countries closer to the polar regions. Finland, for instance, has the highest rate of type 1 diagnosis per year at >60 per 100 000 of the population, whereas in China, India and Venezuela the incidence is only 0.1 per 100 000. Type 1 diabetes is most common in Caucasians, and more people are diagnosed in the winter months.

Diabetes is a major burden on health-care facilities in all countries. Globally, in 2015, diabetes caused 5 million deaths in those aged 20–79 years, and health-care expenditure attributed to diabetes was estimated to be at least 673 billion US dollars, or 12% of total health-care expenditure.

---

Regulation of insulin secretion

Insulin is the primary regulator of glucose metabolism and storage (Box 20.1), and is secreted from pancreatic β cells into the portal circulation (Fig. 20.2). The pancreatic β cell is designed to regulate blood glucose concentrations tightly by coupling glucose and other nutrient stimulus with insulin secretion (Fig. 20.2). Entry of glucose into the pancreatic β cell is by facilitated diffusion down its concentration gradient through cell membrane glucose transporters (GLUTs). Glucose is then metabolised by glycolysis and oxidative phosphorylation. The first step of the glycolytic pathway, the conversion of glucose to glucose-6-phosphate, is catalysed by the enzyme glucokinase (GK). Glucokinase has a low affinity for glucose and so its activity under normal physiological conditions varies markedly, according to the concentration of glucose. This makes it a very effective glucose sensor in the β cell. In what is considered a classical direct or triggering pathway, glucose metabolism results in increased intracellular adenosine triphosphate (ATP) and reduced adenosine diphosphate (ADP) in the β cell, which leads to membrane depolarisation due to opening of voltage-gated calcium channels. This rise in intracellular calcium results in insulin secretion.

Fig. 20.2 Pancreatic structure and endocrine function. A The normal adult pancreas contains about 1 million islets, which are scattered throughout the exocrine parenchyma. Histology is shown in Figure 20.6. B The core of each islet consists of β cells that produce insulin, and is surrounded by a cortex of endocrine cells that produce other hormones, including glucagon (α cells), somatostatin (δ cells) and pancreatic polypeptide (PP cells). C Schematic representation of the pancreatic β cell. (1) Glucose enters the cell via a glucose transporter (GLUT1 or GLUT2). (2) Glucose then enters glycolysis, and subsequent oxidative phosphorylation in the mitochondria results in a rise in intracellular adenosine triphosphate (ATP). (3) This ATP acts to close the KATP channel (which consists of four KIR6.2 subunits and four SUR1 subunits). This leads to membrane depolarisation. (4) The rise in membrane potential results in calcium influx due to opening of a voltage-gated calcium channel. This rise in intracellular calcium causes insulin secretory vesicles to fuse with the cell membrane, leading to insulin secretion. (5) Other stimuli, such as glucagon-like peptide-1 (GLP-1) or gastric inhibitory polypeptide (GIP), act on G-protein-coupled receptors to increase cyclic adenosine monophosphate (cAMP) and amplify the insulin secretion. Genetic defects in the β cell result in diabetes. The primary genes are glucokinase (the initial step in glycolysis) and HNF1α, HNF4α and HNF1β (nuclear transcription factors). Two groups of drugs act on the β cell to promote insulin secretion. Sulphonylureas act to close the KATP channel, causing membrane depolarisation, calcium influx and insulin secretion. Incretin-acting drugs either increase the concentration of endogenous GLP-1 and GIP (the dipeptidyl peptidase 4, or DPP-4, inhibitors) or act as directly on the GLP-1 receptor (GLP-1 receptor agonists). Both of these drug groups act to augment insulin secretion but only following an initial stimulus to insulin secretion through closure of β cell KATP channels by glucose (or sulphonylureas).
An acute first phase of insulin secretion occurs in response to an elevated blood glucose, followed by a sustained second phase. The incretin effect describes the observation that insulin secretion is greater when glucose is given by mouth than when glucose is administered intravenously to achieve the same rise in blood glucose concentrations. The additional stimulus to insulin secretion is mediated by release of peptides from the gut and these actions are exploited in incretin-based therapies (p. 747).

Glucose enters muscle and fat, mediated by the glucose transporter GLUT4. Blood glucose is tightly regulated and maintained within a narrow range. This is essential for ensuring a continuous supply of glucose to the central nervous system. The brain has little capacity to store energy in the form of glycogen or triglyceride, and the blood–brain barrier is largely impermeable to fatty acids, so the brain depends on the liver for a constant supply of glucose for oxidation and hence generation of ATP. Glucose homeostasis is achieved through the coordinated actions of multiple organs, but mainly reflects a balance between the entry of glucose into the circulation from the liver, supplemented by intestinal absorption of glucose after meals, and the uptake of glucose by peripheral tissues, particularly skeletal muscle and brain.

After ingestion of a meal containing carbohydrate, normal blood glucose levels are maintained by:
- suppression of hepatic glucose production
- stimulation of hepatic glucose uptake
- stimulation of glucose uptake by peripheral tissues

Blood glucose homeostasis

Blood glucose is tightly regulated and maintained within a narrow range. This is essential for ensuring a continuous supply of glucose to the central nervous system. The brain has little capacity to store energy in the form of glycogen or triglyceride, and the blood–brain barrier is largely impermeable to fatty acids, so the brain depends on the liver for a constant supply of glucose for oxidation and hence generation of ATP. Glucose homeostasis is achieved through the coordinated actions of multiple organs, but mainly reflects a balance between the entry of glucose into the circulation from the liver, supplemented by intestinal absorption of glucose after meals, and the uptake of glucose by peripheral tissues, particularly skeletal muscle and brain.

After ingestion of a meal containing carbohydrate, normal blood glucose levels are maintained by:
- suppression of hepatic glucose production
- stimulation of hepatic glucose uptake
- stimulation of glucose uptake by peripheral tissues (Fig. 20.5).

The post-prandial rise in portal vein insulin and glucose, together with a fall in portal glucagon concentrations, suppresses hepatic glucose production and results in net hepatic glucose uptake. Depending on the size of the carbohydrate load, around one-quarter to one-third of ingested glucose is taken up in the liver. In addition, insulin stimulates glucose uptake in skeletal muscle and fat, mediated by the glucose transporter GLUT4.
When intestinal glucose absorption declines between meals, portal vein insulin and glucose concentrations fall while glucagon levels rise. This leads to increased hepatic glucose output via gluconeogenesis and glycogen breakdown. The liver now resumes net glucose production and glucose homeostasis is maintained. The main substrates for gluconeogenesis are glycerol and amino acids, as shown in Figure 20.5.

**Fat metabolism**

Adipocytes (and the liver) synthesise triglyceride from non-esterified (‘free’) fatty acids (FFAs) and glycerol. Insulin is the major regulator not only of glucose metabolism but also of fatty acid metabolism. High insulin levels after meals promote triglyceride accumulation. In contrast, in the fasting state, low insulin levels permit lipolysis and the release into the circulation of FFAs (and glycerol), which can be oxidised by many tissues. Their partial oxidation in the liver provides energy to drive gluconeogenesis and also produces ketone bodies (acetoacetate, which can be reduced to 3-hydroxybutyrate or decarboxylated to acetone), which are generated in hepatocyte mitochondria. Ketone bodies are organic acids that, when formed in small amounts, are oxidised and utilised as metabolic fuel. However, the rate of utilisation of ketone bodies by peripheral tissues is limited, and when the rate of production by the liver exceeds their removal, hyperketonaemia results. This occurs physiologically during starvation, when low insulin levels and high catecholamine levels increase lipolysis and delivery of FFAs to the liver.

**Investigations**

**Urine glucose**

Testing the urine for glucose with dipsticks is a common screening procedure for detecting diabetes. If possible, testing should be performed on urine passed 1–2 hours after a meal to maximise sensitivity. Glycosuria always warrants further assessment by blood testing (see below). The greatest disadvantage of urine glucose measurement is the individual variation in renal threshold for glucose. The most frequent cause of glycosuria is a low renal threshold, which is common during pregnancy and in young people; the resulting ‘renal glycosuria’ is a benign condition unrelated to diabetes. Another disadvantage is that some drugs (such as β-lactam antibiotics, levodopa and salicylates) may interfere with urine glucose tests.
**Blood glucose**

Laboratory glucose testing in blood relies on an enzymatic reaction (glucose oxidase) and is cheap, usually automated and highly reliable. However, blood glucose levels depend on whether the patient has eaten recently, so it is important to consider the circumstances in which the blood sample was taken.

Blood glucose can also be measured with testing sticks that are read with a portable electronic meter. These are used for capillary (fingerprick) testing to monitor diabetes treatment that are read with a portable electronic meter. These are used in circumstances in which the blood sample was taken.

Many countries now offer self-monitoring only to people with type 2 diabetes taking sulphonylurea or insulin therapy because of the risk of hypoglycaemia. To make the diagnosis of diabetes, the blood glucose concentration should be estimated using an accurate laboratory method rather than a portable technique.

Glucose concentrations are lower in venous than arterial or capillary (fingeprick) blood. Whole-blood glucose concentrations are lower than plasma concentrations because red blood cells contain relatively little glucose. Venous plasma values are usually the most reliable for diagnostic purposes (Boxes 20.2 and 20.3).

**Interstitial glucose**

A relatively new approach to measuring glucose levels in diabetes is through the use of interstitial continuous glucose monitoring (CGM). CGM systems use a tiny sensor inserted under the skin to check glucose levels in interstitial fluid. The sensor can stay in place for up to 2 weeks before being replaced and provides real-time measurements of glucose levels every 1 or 5 minutes (see Fig. 20.16, p. 751). These devices are not as accurate as blood glucose testing, particularly when levels are low or changing rapidly, so users must still check blood glucose with a glucose meter before driving or changing therapy. CGM provides useful information on daily glucose profiles and, in particular, night-time glucose levels. In addition, alarms can be incorporated into the CGM device to warn individuals about hypoglycaemia.

**Urine and blood ketones**

Acetoacetate can be identified in urine by the nitroprusside reaction, using either tablets or dipsticks. Ketonuria may be found in normal people who have been fasting or exercising strenuously for long periods, vomiting repeatedly, or eating a diet high in fat and low in carbohydrate. Ketonuria is therefore not pathognomonic of diabetes but, if it is associated with glycosuria, the diagnosis of diabetes is highly likely. Urine ketone measurements are semi-quantitative, awkward to perform and retrospective (i.e. the urine has accumulated over several hours). Also, they do not measure the major ketone found in blood during diabetic ketoacidosis (DKA), beta-hydroxybutyrate (β-OHB). Beta-OHB can be measured in blood in the laboratory and also in a fingerprick specimen of capillary blood with a test stick and electronic meter. Whole-blood β-OHB monitoring is useful in assisting with insulin adjustment during intercurrent illness or sustained hyperglycaemia to prevent or detect DKA. Blood β-OHB monitoring is also useful in monitoring resolution of DKA in hospitalised patients (Box 20.4).

**Glycated haemoglobin**

Glycated haemoglobin provides an accurate and objective measure of glycaemic control over a period of weeks to months.

In diabetes, the slow non-enzymatic covalent attachment of glucose to haemoglobin (glycation) increases the amount in the HbA1c fraction relative to non-glycated adult haemoglobin (HbA0). These fractions can be separated by chromatography.

### 20.2 Diagnosis of diabetes and pre-diabetes

**Diabetes is confirmed by:**

- either plasma glucose in random sample or 2 hrs after a 75 g glucose load ≥11.1 mmol/L (200 mg/dL) or
- fasting plasma glucose ≥7.0 mmol/L (126 mg/dL) or
- HbA1c ≥48 mmol/mol

In asymptomatic patients, two diagnostic tests are required to confirm diabetes; the second test should be the same as the first test to avoid confusion.

‘Pre-diabetes’ is classified as:

- impaired fasting glucose = fasting plasma glucose ≥6.1 mmol/L (110 mg/dL) and ≤7.7 mmol/L (139 mg/dL)
- impaired glucose tolerance = fasting plasma glucose < 7.0 mmol/L (126 mg/dL) and 2-hr glucose after 75 g oral glucose drink 7.8–11.1 mmol/L (140–200 mg/dL)

HbA1c criteria for pre-diabetes vary. The National Institute for Health and Care Excellence (NICE) guidelines (UK) recommend considering an HbA1c range of 42–47 mmol/mol to be indicative of pre-diabetes; the American Diabetes Association (ADA) guidelines suggest a range of 39–47 mmol/mol. The ADA also suggests a lower fasting plasma glucose limit of ≥5.6 mmol/L (100 mg/dL) for impaired fasting glucose.

### 20.3 How to perform an oral glucose tolerance test (OGTT)

#### Preparation before the test

- Unrestricted carbohydrate diet for 3 days
- Fasted overnight for at least 8 hrs
- Rest for 30 mins
- Remain seated for the duration of the test, with no smoking

#### Sampling

- Measure plasma glucose before and 2 hrs after a 75 g oral glucose drink

### 20.4 Interpretation of capillary blood ketone measurements

<table>

</tr>
</tbody>
</table>

*To convert to mg/dL, multiply values by 18.
laboratories may report glycated haemoglobin as total glycated haemoglobin (GHb), HbA1, or HbA1c. In most countries, HbA1c is the preferred measurement. The rate of formation of HbA1c is directly proportional to the ambient glucose concentration; a rise of 11 mmol/mol in HbA1c corresponds to an approximate average increase of 2 mmol/L (36 mg/dL) in blood glucose. Although HbA1c concentration reflects the integrated blood glucose control over the lifespan of erythrocytes (120 days), HbA1c is most sensitive to changes in glycaemic control occurring in the month before measurement.

Various assay methods are used to measure HbA1c, but most laboratories have been reporting HbA1c values (as %) aligned with the reference range that was used in the Diabetes Control and Complications Trial (DCCT). To allow worldwide comparisons of HbA1c values, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has developed a standard method; IFCC-standardised HbA1c values are reported in mmol/mol. In 2011, many countries adopted the IFCC reference method (Box 20.5) and this is used throughout this textbook.

HbA1c estimates may be erroneously diminished in anaemia or during pregnancy, and may be difficult to interpret with some assay methods in patients who have haemoglobinopathy. It is particularly important to be aware of this in some developing countries where nutritional deficiency is common, especially when an absolute cut-off point is used, e.g. in the diagnosis of diabetes.

### 20.5 Conversion between DCCT and IFCC units for HbA1c

IFCC HbA1c (mmol/mol) = [DCCT HbA1c(%)–2.15] × 10.929

(DCCT = Diabetes Control and Complications Trial; IFCC = International Federation of Clinical Chemistry and Laboratory Medicine)

Glycaemia can be classified into three categories: normal, impaired (pre-diabetes) and diabetes (see Box 20.2). The glycaemia cut-off that defines diabetes is based on the level above which there is a significant risk of microvascular complications (retinopathy, nephropathy and neuropathy). People categorised as having pre-diabetes have blood glucose levels that carry a negligible risk of microvascular complications but are at increased risk of developing diabetes. Also, because there is a continuous risk of macrovascular disease (atheroma of large conduit blood vessels) with increasing glycaemia in the population, people with pre-diabetes have an increased risk of cardiovascular disease (myocardial infarction, stroke and peripheral vascular disease).

The traditional way to diagnose diabetes or pre-diabetes has been by using random or fasting plasma glucose and/or an oral glucose tolerance test (OGTT). In 2011, the World Health Organisation (WHO) advocated the use of glycated haemoglobin (HbA1c, see above) to diagnose diabetes and this has been adopted in some regions. When a person has symptoms of diabetes, the diagnosis can be confirmed with either a fasting glucose of ≥7.0 mmol/L (126 mg/dL) or a random glucose of ≥11.1 mmol/L (200 mg/dL) (see Box 20.2). Asymptomatic individuals should have a second confirmatory test. Diabetes should not be diagnosed on capillary blood glucose results. Alternatively, an HbA1c of ≥48 mmol/mol is also diagnostic of diabetes. As HbA1c reflects the last 2–3 months of glycaemia, it should not be used to diagnose diabetes where the duration of onset is short, i.e. in someone with suspected type 1 diabetes or severe symptomatic hyperglycaemia (p. 734). If there is a high clinical suspicion of diabetes with an HbA1c of less than 48 mmol/mol, then a fasting glucose measurement is required to rule out diabetes. It should be noted that the two populations identified using blood glucose and using HbA1c will not be identical, some
being diagnosed with diabetes using one criterion but not the other. When a person is asymptomatic and repeat testing is required, the same method should be used for the confirmatory test to avoid diagnostic confusion.

Pre-diabetes can be subclassified as ‘impaired fasting glucose’ (IFG), based on a fasting plasma glucose result, or ‘impaired glucose tolerance’ (IGT), based on the fasting and 2-hour OGTT results (see Box 20.3). Patients with pre-diabetes should be advised of their risk of progression to diabetes, given advice about lifestyle modification to reduce this risk (as for type 2 diabetes, p. 743), and have aggressive management of cardiovascular risk factors such as hypertension and dyslipidaemia. The HbA1c criteria for pre-diabetes are less clear. The NICE guidelines (UK) suggest a range of 42–47 mmol/mol, whereas the American Diabetes Association guidelines recommend a range of 59–74 mmol/mol.

In some people (especially those with pre-existing insulin resistance or low β-cell mass/function), an abnormal blood glucose result is observed during acute severe illness, such as infection or myocardial infarction. This ‘stress hyperglycaemia’ is a consequence of hormones, such as cortisol and catecholamines, antagonising the action of insulin and thereby increasing insulin resistance. It usually disappears after the acute illness has resolved, but affected individuals have a significantly increased risk of type 2 diabetes in subsequent years. A similar mechanism explains the occurrence of diabetes in some people treated with glucocorticoids (steroid-induced diabetes).

The diagnostic criteria recommended for diabetes in pregnancy are more stringent than those for non-pregnant patients (see Box 20.31). Pregnant women with abnormal glucose tolerance should be referred urgently to a specialist unit for full evaluation. Due to the increased red cell turnover that occurs in pregnancy, an HbA1c test should not be used to diagnose diabetes in pregnancy.

When a diagnosis of diabetes is confirmed, other investigations should include plasma urea, creatinine and electrolytes, lipids, liver and thyroid function tests, blood or urine ketones, and urine protein.

Aetiology and pathogenesis of diabetes

In both of the common types of diabetes, environmental factors interact with genetic susceptibility to determine which people develop the clinical syndrome, and the timing of its onset. However, the underlying genes, precipitating environmental factors and pathophysiology differ substantially between type 1 and type 2 diabetes. Type 1 diabetes was previously termed ‘insulin-dependent diabetes mellitus’ (IDDM) and is invariably associated with insulin deficiency requiring replacement therapy. Type 2 diabetes was previously termed ‘non-insulin-dependent diabetes mellitus’ (NIDDM) because patients retain the capacity to secrete insulin, and measured insulin levels are often higher than those seen in people without diabetes. In type 2 diabetes, though, there is an impaired sensitivity to insulin (insulin resistance) and, initially, affected individuals can usually be treated without insulin replacement therapy. However, 20% or more of patients with type 2 diabetes will ultimately develop insulin deficiency requiring replacement therapy, so IDDM and NIDDM were misnomers.

Type 1 diabetes

Pathology

Type 1 diabetes is generally considered a T-cell-mediated autoimmune disease (p. 81) involving destruction of the insulin-secreting β cells in the pancreatic islets. The natural history of type 1 diabetes is based on the model proposed by Eisenbarth in 1986, which proposed that genetically susceptible individuals with a given β-cell mass who were subsequently exposed to an environmental trigger then developed β-cell autoimmunity that led to progressive loss of β cells. This process was seen to take place over a prolonged period (months to years). Marked hyperglycaemia, accompanied by the classical symptoms of diabetes, occurs only when 80–90% of the functional capacity of β cells has been lost. More recent data have led to modifications of this model. For example, it is now recognised that pancreatic β cells can persist in some individuals with very long-standing diabetes and may never reach zero. On the contrary, some individuals present with much higher levels of β-cell viability (40–50%) and that may reflect lower levels of physical activity or increased body mass. Despite this uncertainty, in the natural history of type 1 diabetes there is initially a loss of first-phase insulin secretion, followed by a period of glucose intolerance and clinically undiagnosed diabetes.

The pathology in the pre-diabetic pancreas is characterised by an inflammatory lesion within islets, ‘insulitis’ (Fig. 20.6), with infiltration of the islets by mononuclear cells containing activated macrophages, helper cytotoxic and suppressor T lymphocytes, natural killer cells and B lymphocytes. Initially, these lesions are patchy and, until a very late stage, lobules containing heavily infiltrated islets are seen adjacent to unaffected lobules. The destructive process is β-cell-specific. It is unclear why other hormone-secreting cells in the islets, such as α and δ cells, remain intact. In addition, while a number of theories such as molecular mimicry, oxidative stress and viral infections have been proposed, the specific mechanisms for inducing autoimmunity in type 1 diabetes are unknown.

Autoimmunity in type 1 diabetes is identified by the presence of autoantibodies to islet and/or β-cell antigens. Islet cell antibodies can be present long before the clinical presentation of type 1 diabetes, and their detection can be useful in confirming a diagnosis of type 1 diabetes, but they are poorly predictive of disease progression and disappear over time (Fig. 20.6). Autoantibodies are typically present in 70–80% of newly diagnosed type 1 diabetes, but this can vary depending on age, gender and ethnicity, as well as quality of the assay employed. Autoantibodies can also be used to predict disease with a 5-year risk of type 1 diabetes of about 20–25% in people with a single positive autoantibody, 50–60% in those with two positive autoantibodies, and 70% in those with three autoantibodies. Type 1 diabetes is associated with other autoimmune disorders (Ch. 4), including thyroid disease (p. 639), coeliac disease (p. 805), Addison’s disease (p. 671), pernicious anaemia (p. 944) and vitiligo (p. 1257). The association between type 1 diabetes and coeliac disease is particularly strong; it is estimated that around 1 in 20 people with type 1 diabetes (especially when diagnosed in childhood) will have biopsy-proven coeliac disease and so many countries advocate routine screening for this condition.

Genetic predisposition

Although not showing a simple pattern of inheritance, type 1 diabetes is strongly influenced by genetic factors. The relationship is complex and, as indicated, multifactorial. Monozygotic twins have a disease concordance rate of 30–50%, while dizygotic twins have a concordance of 6–10%. In the USA, the risk of developing type 1 diabetes is 1:20 for those with a first-degree relative, compared with a 1:300 risk in the general population. Children of mothers with type 1 diabetes have a 1–4% risk of
developing type 1 diabetes, but children of fathers with type 1 diabetes have a 10% risk. Despite this genetic influence, 80–85% of new cases present in individuals with no known family history of the disease.

The inheritance of type 1 diabetes is polygenic (Box 20.6), with over 20 different regions of the human genome showing an association with type 1 diabetes risk. Most interest has focused on the human leucocyte antigen (HLA) region within the major histocompatibility complex on the short arm of chromosome 6. The HLA haplotypes DR3 and/or DR4 are associated with increased susceptibility to type 1 diabetes in Caucasians and are in ‘linkage disequilibrium’, i.e. they tend to be transmitted together, with the neighbouring alleles of the HLA-DQA1 and DQB1 genes. The latter may be the main determinants of genetic susceptibility, since these HLA class II genes code for proteins on the surface of cells that present foreign and self-antigens to T lymphocytes (p. 82). Candidate gene and genome-wide association studies have also implicated other genes in type 1 diabetes, e.g. CD25, PTPN22, SH2B3, IL2RA and IL-10. Interestingly, the majority of these disease risk loci are involved in immune responsiveness, such as recognition of pancreatic islet antigens, T-cell development and immune regulation. The genes associated with type 1 diabetes overlap with those for other autoimmune disorders, such as coeliac disease and thyroid disease, consistent with clustering of these conditions in individuals or families.

**Environmental predisposition**

The wide geographical and seasonal variations in incidence, and the rapid acquisition of local disease incidence rates in migrants from low- to high-incidence countries suggest that environmental factors have an important role in precipitating disease.

Although hypotheses abound, the nature of these environmental factors is unknown. They may trigger type 1 diabetes through direct toxicity to β cells or by stimulating an autoimmune reaction directed against β cells. Potential candidates fall into three main categories: viruses, specific drugs or chemicals, and dietary constituents. Viruses implicated in the aetiology of type 1 diabetes include mumps, Coxsackie B4, retroviruses, rubella (in utero), cytomegalovirus and Epstein–Barr virus. Various dietary nitrosamines (found in smoked and cured meats) and coffee have been proposed as potentially diabetogenic toxins. Bovine serum albumin (BSA), a major constituent of cow’s milk, has been implicated, since children who are given cow’s milk early in infancy are more likely to develop type 1 diabetes than those who are breastfed. BSA may cross the neonatal gut and raise antibodies that cross-react with a heat-shock protein expressed by β cells. It has also been proposed that reduced exposure to microorganisms in early childhood limits maturation of the immune system and increases susceptibility to autoimmune disease (the ‘hygiene hypothesis’). In addition, the high incidence rates in northern Europe have led to the suggestion that low levels of vitamin D may be important, but to date no clear cause–effect relationship has been identified.

**Metabolic disturbances in type 1 diabetes**

Patients with type 1 diabetes present when progressive β-cell destruction has crossed a threshold at which adequate insulin secretion and normal blood glucose levels can no longer be sustained. Above a certain level, high glucose levels may be toxic to the remaining β cells, so that profound insulin deficiency rapidly ensues, causing the metabolic sequelae shown in Figure 20.7. Hyperglycaemia leads to glycosuria and dehydration, causing fatigue, polyuria, nocturia, thirst and polydipsia, susceptibility to urinary and genital tract infections, and later tachycardia and hypotension. Unrestrained lipolysis and proteolysis result in
weight loss. Ketoacidosis occurs when generation of ketones exceeds the capacity for their metabolism. Elevated blood \(H^+\) ions drive \(K^+\) out of the intracellular compartment, while secondary hyperaldosteronism encourages urinary loss of \(K^+\). Thus patients usually present with a short history (typically a few weeks) of hyperglycaemic symptoms (thirst, polyuria, nocturia and fatigue), infections and weight loss, and may have developed ketoacidosis (p. 735).

**Type 1 diabetes in adults**

While type 1 diabetes is classically thought of as a disease of children and young adults (most commonly presenting between 5 and 7 years of age and at or near puberty), it can manifest at any age, with as much as half of cases thought to develop in adults. It is also possible for patients who have a more insidious onset of diabetes to have an autoimmune aetiology; these people are sometimes described as having slow-onset type 1 diabetes or latent autoimmune diabetes of adulthood (LADA). LADA is defined as the presence of islet autoantibodies in high titre (usually GAD antibodies), without rapid progression to insulin therapy (which would usually signify type 1 diabetes). Patients with LADA can often present and be managed similarly to those with type 2 diabetes, but they do progress more rapidly to requiring insulin treatment for glucose control. Not all expert committees recognise LADA as a diagnostic category, however, and consider LADA to be just a subset of autoimmune type 1 diabetes developing in adulthood.

**Type 2 diabetes**

**Pathology**

Type 2 diabetes is a diagnosis of exclusion, i.e. it is made when type 1 diabetes and other types of diabetes (see Box 20.9) are ruled out; it is highly heterogeneous. The natural history of typical type 2 diabetes is shown in Figure 20.8. Initially, insulin resistance leads to elevated insulin secretion in order to maintain normal blood glucose levels. However, in susceptible individuals, the pancreatic \(\beta\) cells are unable to sustain the increased demand for insulin and a slowly progressive insulin deficiency develops. Some patients develop diabetes at a young age, usually driven by insulin resistance due to obesity and ethnicity; others, particularly older patients, develop diabetes despite being non-obese and may have more pronounced \(\beta\)-cell failure. The key feature is a ‘relative’ insulin deficiency, such that there is insufficient insulin production to overcome the resistance to insulin action. This contrasts with type 1 diabetes, in which there is rapid loss of insulin production, resulting in ketoacidosis and death if the insulin is not replaced.

**Insulin resistance and the metabolic syndrome**

Type 2 diabetes and its pre-diabetes antecedents belong to a cluster of conditions thought to be caused by resistance to insulin action. Thus, people with type 2 diabetes often have associated disorders including hypertension, dyslipidaemia (characterised by elevated levels of small dense low-density lipoprotein (LDL))
In the early stage of the disorder, the response to progressive insulin resistance is an increase in insulin secretion by the pancreatic cells, causing hyperinsulinaemia. Eventually, the β-cells are unable to compensate adequately and blood glucose rises, producing hyperglycaemia. With further β-cell failure, glycaemic control deteriorates and treatment requirements escalate.

Progressive pancreatic β-cell failure in patients with type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS). Beta-cell function was estimated using the homeostasis model assessment (HOMA) and was already below 50% at the time of diagnosis. Thereafter, long-term incremental increases in fasting plasma glucose were accompanied by progressive β-cell dysfunction. If the slope of this progression is extrapolated, it appears that pancreatic dysfunction may have been developing for many years before diagnosis of diabetes.

Fig. 20.8 Natural history of type 2 diabetes. A In the early stage of the disorder, the response to progressive insulin resistance is an increase in insulin secretion by the pancreatic cells, causing hyperinsulinaemia. Eventually, the β-cells are unable to compensate adequately and blood glucose rises, producing hyperglycaemia. B Progressive pancreatic β-cell failure in patients with type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS). Beta-cell function was estimated using the homeostasis model assessment (HOMA) and was already below 50% at the time of diagnosis. Thereafter, long-term incremental increases in fasting plasma glucose were accompanied by progressive β-cell dysfunction. If the slope of this progression is extrapolated, it appears that pancreatic dysfunction may have been developing for many years before diagnosis of diabetes. B, Adapted from Holman RR. Diabetes Res Clin Pract 1998; 40 (Suppl.):S21–S25.

Aetiology and pathogenesis of diabetes • 731

cholesterol and triglycerides, and a low level of high-density lipoprotein (HDL) cholesterol, non-alcoholic fatty liver disease (p. 882) and, in women, polycystic ovarian syndrome. This cluster has been termed the ‘insulin resistance syndrome’ or ‘metabolic syndrome’, and is much more common in individuals who are obese.

The primary cause of insulin resistance remains unclear; it is likely that there are multiple defects in insulin signalling, affecting several tissues. One theory is centred around the adipocyte; this is particularly appealing, as obesity is a major cause of increased insulin resistance. Intra-abdominal ‘central’ adipose tissue is metabolically active and releases large quantities of FFAs, which may induce insulin resistance because they compete with glucose as a fuel supply for oxidation in peripheral tissues such as muscle. In addition, adipose tissue releases a number of hormones (including a variety of peptides, called ‘adipokines’) that act on specific receptors to influence sensitivity to insulin in other tissues. Because the venous drainage of visceral adipose tissue is into the portal vein, central obesity may have a particularly potent influence on insulin sensitivity in the liver, and thereby adversely affect gluconeogenesis and hepatic lipid metabolism.

Physical activity is another important determinant of insulin sensitivity. Inactivity is associated with down-regulation of insulin-sensitive kinases and may promote accumulation of FFAs within skeletal muscle. Sedentary people are therefore more insulin-resistant than active people with the same degree of obesity. Moreover, physical activity allows non-insulin-dependent glucose uptake into muscle, reducing the ‘demand’ on the pancreatic β-cells to produce insulin.

Deposition of fat in the liver is a common association with central obesity and is exacerbated by insulin resistance and/or deficiency. Many people with type 2 diabetes have evidence of fatty infiltration of the liver (non-alcoholic fatty liver disease, NAFLD). This condition may improve with effective treatment of the diabetes but, despite this, some patients progress to non-alcoholic steatohepatitis (NASH, p. 882) and cirrhosis.

Pancreatic β-cell failure

In the early stages of type 2 diabetes, reduction in the total mass of pancreatic islet tissue is modest. At the time of diagnosis, around 50% of β-cell function has been lost and this declines progressively (Fig. 20.8B). Some pathological changes are typical of type 2 diabetes, the most consistent of which is deposition of amyloid in the islets. In addition, elevated plasma glucose and FFAs exert toxic effects on pancreatic β-cells to impair insulin secretion. However, while β-cell mass is unchanged and glucagon secretion is increased, which may contribute to hyperglycaemia.

Genetic predisposition

Genetic factors are important in type 2 diabetes, as shown by marked differences in susceptibility in different ethnic groups and by studies in monozygotic twins where concordance rates for type 2 diabetes approach 100%. However, many genes are involved and the chance of developing diabetes is also influenced very powerfully by environmental factors (Box 20.7). Genome-wide association studies have identified over 70 genes...
or gene regions that are associated with type 2 diabetes, each exerting a small effect. Most of the genes known to contribute to risk of type 2 diabetes are involved in β-cell function or in regulation of cell cycling and turnover, suggesting that altered regulation of β-cell mass is a key factor. The largest population genetic effect described to date is seen with variation in TCF7L2: the 10% of the population with two copies of the risk variant for this gene have a nearly twofold increase in risk of developing type 2 diabetes. In general, other common variants explain much lower risk than this, many explaining less than a 10% increase in risk only; as only about 10% of the genetic variance in type 2 diabetes is explained by these common genetic variants, this has led some to question the relevance of finding diabetes genes. However, it should be noted that, within a population, the distribution of risk variants will vary, with some patients having inherited a high genetic burden (e.g. more than 40 risk variants) and others having inherited very few. When studies compare those in the top 20% of this risk band with the lowest 20%, those at highest risk are over 2.5 times more likely to develop diabetes. More recent insights into the genetics of type 2 diabetes have highlighted how some genetic variants may be rare and therefore affect only a small proportion of the population, but have large clinical effects. For example, in a Greenlandic population, 3% of people carry a homozygous variant in an insulin signalling gene, TBC1D4, that results in muscle insulin resistance; these individuals are over 10 times more likely to develop type 2 diabetes.

**Environmental and other risk factors**

**Diet and obesity**

Epidemiological studies show that type 2 diabetes is associated with overeating, especially when combined with obesity and under-activity. Middle-aged people with diabetes eat significantly more and are fatter and less active than their non-diabetic siblings. The risk of developing type 2 diabetes increases 10-fold in people with a body mass index (BMI) of more than 30 kg/m² (p. 698). However, although the majority of individuals with type 2 diabetes are obese, only a minority of obese people develop diabetes, as most obese people are able to increase insulin secretion to compensate for the increased demand resulting from obesity and insulin resistance. Those who develop diabetes may have genetically impaired β-cell function, reduced β-cell mass, or a susceptibility of β cells to attack by toxic substances such as FFAs or inflammatory cytokines.

**Age**

Type 2 diabetes is more common in middle-aged and older individuals (Box 20.8). In the UK, it affects 10% of the population over 65, and over 70% of all cases of diabetes occur after the age of 50 years.

**20.8 Diagnosis of diabetes mellitus in old age**

- **Prevalence:** increases with age, affecting ~10% of people over 65 years. Half of these are undiagnosed. Impaired β-cell function and exaggerated insulin resistance with ageing both contribute.
- **Glycosuria:** the renal threshold for glucose rises with age, so glycosuria may not develop until the blood glucose concentration is markedly raised.
- **Pancreatic carcinoma:** may present in old age with the development of diabetes, in association with weight loss and diminished appetite.

**Ethnicity**

Ethnic origin is a major risk factor for development of diabetes. For example, within the USA, the prevalence of diabetes is lowest in Alaskan Natives at 5.5%, moderate for non-Hispanic whites at 7.1%, high for non-Hispanic blacks at 13% and highest in Native Americans at 33%. This considerable variation in prevalence reflects a number of different factors, including a higher BMI and lower socioeconomic class in high-risk groups in the USA; differences in health behaviour, e.g. decreased physical activity and increased smoking; and differences in genetic risk. Studies in high-risk ethnic groups largely demonstrate increased insulin resistance and more central/visceral adiposity than in the lower-risk groups.

**Metabolic disturbances in type 2 diabetes**

Patients with type 2 diabetes have a slow onset of ‘relative’ insulin deficiency. Relatively small amounts of insulin are required to suppress lipolysis, and some glucose uptake is maintained in muscle so that, in contrast to type 1 diabetes, lipolysis and proteolysis are not unrestrained and weight loss and ketoacidosis seldom occur. In type 2 diabetes, hyperglycaemia tends to develop slowly over months or years; because of this insidious onset many cases of type 2 diabetes are discovered coincidently and a large number are undetected. At diagnosis, patients are often asymptomatic or give a long history (typically many months) of fatigue, with or without ‘osmotic symptoms’ (thirst and polyuria). However, there are some people with type 2 diabetes who present acutely with marked osmotic symptoms and weight loss. These may be presenting late, such that they have already developed β-cell failure, but more usually this decompensation reflects a vicious spiral of decline. As hyperglycaemia worsens, patients often crave sugar and will consume large volumes of sugary drinks to try to quench their thirst; worsening hyperglycaemia is also associated with increasing lipolysis, and the high circulating glucose and FFAs are toxic to the β cell, resulting in ‘gluolipotoxicity’ and reduced β-cell function. In these patients, ketosis and even DKA can occur; this is classically described in the African American population, where up to half of patients who present with DKA have type 2 diabetes and not type 1 diabetes. The presentation of DKA in type 2 diabetes is referred to as ‘ketosis-prone’ diabetes or ‘Flatbush syndrome’, named after the Flatbush neighbourhood of New York, which had a large Caribbean population and where presentation with DKA was common. Importantly in these patients, insulin treatment is required initially but, as the glucose and lipids are controlled, the β cells recover, and they can usually transfer off insulin and on to oral treatments such as metformin after 3 months of insulin treatment.

Intercurrent illness, e.g. with infections, increases the production of stress hormones that oppose insulin action, such as cortisol, growth hormone and catecholamines. This can precipitate an acute exacerbation of insulin resistance and insulin deficiency, and result in more severe hyperglycaemia and dehydration (p. 738).

**Other forms of diabetes**

Other causes of diabetes are shown in Box 20.9. These can broadly be broken down into genetic disorders including monogenic diabetes (diabetes due to a mutation in or deletion of a single gene) or diabetes as part of a genetic syndrome; endocrine disorders due to excess in hormones that oppose
secondary to alcohol excess can be managed with oral therapy, endocrine failure. While diabetes due to pancreatic insufficiency and recurrent abdominal pain, it is asymptomatic in many patients, resulting in both pancreatic exocrine failure and diabetes. However, more commonly, chronic alcohol excess can cause recurrent bouts of acute pancreatitis, with progressive destruction of the pancreas and subsequent diabetes. The set point for basal insulin release is altered, causing a high fasting glucose, but insufficient insulin is released after meals. As a result, the HbA1c is often normal and microvascular complications are rare. Treatment is rarely required.

Diabetes develops during adolescence/early adulthood and can be managed with diet and tablets for many years, but ultimately, insulin treatment is required. The HNF1α and 4α forms respond particularly well to sulphonylurea drugs. All types are associated with microvascular complications. HNF1β mutations also cause renal cysts and renal failure.

*Other gene mutations have been found in rare cases. For further information, see diabetesgenes.org.

### Monogenic diabetes

Monogenic diabetes accounts for approximately 4% of diabetes in those diagnosed under the age of 30 in the UK. While there are a number of monogenic disorders of insulin action, the most common monogenic forms of diabetes are caused by defects in insulin secretion, in part because insulin resistance alone is not sufficient to cause diabetes. Monogenic disorders of the β cell cause two diabetes subtypes: maturity-onset diabetes of the young (MODY; Box 20.10) and neonatal diabetes. The common genes involved in MODY and neonatal diabetes are shown in Figure 20.2C.

MODY is defined as non-insulin-requiring diabetes that develops under the age of 25 years in one family member. MODY is dominantly inherited (p. 46), which means that the diabetes runs in families, many having a family history of diabetes spanning three generations or more. MODY itself is a heterogeneous condition, with multiple subtypes. One form is caused by mutations in glucokinase (see Fig. 20.2B); this is the pancreatic glucose sensor and patients with glucokinase mutations have an altered set-point for glucose. This results in a high fasting glucose (usually >5.5 mmol/L (99 mg/dL)) but a normal post-prandial response. As a result, patients with glucokinase MODY have stable, mild hyperglycaemia, with only a slightly elevated HbA1c; they do not require treatment and do not develop diabetes complications. It is therefore important to identify these patients, to avoid unnecessary diabetes treatment and monitoring. The other forms of MODY are mostly caused by defective transcription factors that play a key role in pancreatic β-cell development and function (hepatocyte nuclear factor (HNF) 1α, 1β and 4α). Patients with transcription factor MODY develop diabetes in adolescence or early adulthood and the diabetes is progressive, requiring oral diabetes treatment before eventually needing insulin. Patients with HNF1α and 4α MODY are extremely sensitive to sulphonylureas and this is the treatment of choice for these individuals. HNF1β is a critical transcription factor not only in pancreatic development but also in renal and genital tract development in utero. Patients with HNF1β mutations usually have renal abnormalities, including renal cystic disease and genital tract malformation, such as absent or bicornuate uterus or hypospadias and infertility; about 50% of individuals with the gene mutation have young-onset diabetes.
Neonatal diabetes is variably defined as diabetes that presents in the neonatal period, although this is usually extended to the first 6 months of life. The presentation is usually that of profound insulin deficiency with marked hyperglycaemia and DKA. Approximately half of patients with neonatal diabetes have a transient form that remits by about 1 year of age, with diabetes recurring in adolescence or early adulthood; the remaining patients have permanent neonatal diabetes. In recent years, the genetics of neonatal diabetes have been unravelled, having a major positive impact for people with this condition. Approximately two-thirds of patients with permanent neonatal diabetes have an activating mutation in the genes encoding the K(IR)6.2 and SUR1 subunits of the KATP channel (see Fig. 20.2C). These mutations cause the KATP channel to be insensitive to the glucose-mediated rise in intracellular ATP; as a result, the pancreatic β cells do not secrete insulin and patients require insulin treatment from soon after birth. It has been shown, however, that these individuals do respond to sulphonylureas; this finding has transformed their care, over 90% being managed with oral sulphonylurea treatment.

**Presenting problems in diabetes mellitus**

**Hyperglycaemia**

The diagnosis of diabetes is simple: it is based on confirmation of hyperglycaemia using either fasting or random glucose, an OGTT or HbA1c (p. 727). Diabetes, however, results from a variety of pathological processes, meaning that within this broad category are many aetiological subtypes. Following the identification of hyperglycaemia and subsequent diagnosis of diabetes, the initial management involves a careful clinical assessment of the patient to decide whether immediate treatment is required and, with appropriate investigation, to establish the aetiology of the diabetes, as this will determine subsequent diabetes treatment (Fig. 20.9). The main differential diagnosis to consider is that of type 1 or type 2 diabetes; making a diagnosis of type 1 diabetes is important, as a failure to initiate insulin treatment can result in death.

**New-onset hyperglycaemia**

Confirm diagnosis of diabetes (Box 20.2)

| Patient unwell and/or Marked symptoms of hyperglycaemia and/or Blood ketones elevated | Refer for immediate assessment Evaluate for DKA/HHS and intercurrent illness – see emergency management |
| Comence IV insulin and fluids | Commence SC insulin |
| Continue on SC insulin | Evaluate aetiology of diabetes* |
| Likely type 1 diabetes | Likely type 2 diabetes |
| Continue on insulin | Consider introducing oral agents and weaning insulin (careful monitoring required) |

Possible type 1 diabetes?

Self-monitoring of blood glucose and ketones

Low threshold to start SC insulin

Evaluate aetiology of diabetes* |

Probable type 2 diabetes?

Diet and lifestyle modification Early initiation of metformin

Manage according to diabetes aetiology

*Evaluation of diabetes aetiology

**Typical type 1 diabetes?**

- Not overweight
- No family history of diabetes
- GAD/IA-2 antibody-positive
- Low C-peptide

**Typical type 2 diabetes?**

- Obese or overweight
- Aged over 40
- Family history of diabetes
- Ethnicity high diabetes risk
- GAD/IA-2 antibody-negative
- Elevated C-peptide
- No other cause

**Other types?**

- Chronic pancreatitis/abdominal pain – consider alcohol-related or pancreatic malignancy
- Features of endocrine disease?
- Abnormal liver function – consider haemochromatosis
- Three-generation family history – consider monogenic diabetes
- Renal and urinary tract abnormalities – consider HNF1β

Fig. 20.9 New-onset hyperglycaemia. (DKA = diabetic ketoacidosis; GAD = glutamic acid decarboxylase; HHS = hyperosmotic hyperglycaemic state; IA-2 = islet antigen 2; IV = intravenous; SC = subcutaneous)
the development of DKA and death. If the aetiological diagnosis is in doubt, it is important not to delay insulin treatment, which can be withdrawn subsequently if necessary.

Hyperglycaemia causes a wide variety of symptoms (Box 20.11). The classical clinical features of type 1 and type 2 diabetes are compared in Box 20.12. Symptoms of polydipsia, polyuria, nocturia and rapid weight loss are prominent in type 1 diabetes but are often absent in patients with type 2 diabetes, many of whom are asymptomatic or have non-specific complaints such as chronic fatigue and malaise. Uncontrolled diabetes is associated with an increased susceptibility to infection and patients may present with skin sepsis (boils) or genital candidiasis, and complain of pruritus vulvae or balanitis.

While the distinction between type 1 and type 2 diabetes is usually obvious, overlap occurs, particularly in age at onset, duration of symptoms and family history. There are many patients in whom the type of diabetes is not immediately apparent. For example, patients with type 2 diabetes may present with marked and rapid weight loss and even DKA (10–15% of all cases of DKA), and type 2 diabetes is increasingly diagnosed in children and young adults. Type 1 diabetes can occur at any age, not just in younger people, and may develop more insidiously; the presence of pancreatic autoantibodies confirms the diagnosis of slow-onset type 1 diabetes or LADA. Islet autoantibodies are detectable at high titre in many patients with type 1 diabetes, so a negative result should prompt consideration of other aetiologies. Other causes of diabetes (see Box 20.9), such as MODY, should not be forgotten, particularly in those presenting in childhood or as young adults. A history of pancreatic disease, particularly in patients with a history of alcohol excess, makes insulin deficiency more likely.

Sometimes the definitive classification of the type of diabetes is only made later, once the natural history or responsiveness to different therapies becomes apparent.

Physical signs in patients with type 2 diabetes at diagnosis depend on the mode of presentation. In Western populations, more than 80% are overweight and the obesity is often central (truncal or abdominal). Obesity is much less evident in Asians. Hypertension is present in at least 50% of patients with type 2 diabetes. Although dyslipidaemia is also common, skin lesions such as xanthelasma and eruptive xanthomas are rare.

### Presentation with the complications of diabetes

Patients with long-standing diabetes are at risk of developing a variety of complications (see Box 20.35, p. 756) and as many as 25% of people with type 2 diabetes have evidence of diabetic complications at the time of diagnosis. Thus, diabetes may be first suspected when a patient visits an optometrist or podiatrist, or presents with hypertension or a vascular event such as an acute myocardial infarction or stroke. Blood glucose should therefore be checked in all patients presenting with such pathology. The detailed investigation and management of diabetic complications are described on page 755.

### Diabetes emergencies

#### Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is a medical emergency and remains a serious cause of morbidity, principally in people with type 1 diabetes. Mortality is low in the UK (approximately 2%) but remains high in developing countries and among non-hospitalised patients. Mortality in DKA is most commonly caused in children and adolescents by cerebral oedema, and in adults by hypokalaemia, acute respiratory distress syndrome and comorbid conditions such as acute myocardial infarction, sepsis or pneumonia.

DKA is characteristic of type 1 diabetes (see Box 20.12) and is often the presenting problem in newly diagnosed patients. However, an increasing number of patients presenting with DKA have underlying type 2 diabetes. This appears to be particularly prevalent in black and non-Hispanic populations. In established type 1 diabetes, DKA may be precipitated by an intercurrent illness because of failure to increase insulin dose appropriately to compensate for the stress response. Sometimes, there is no evidence of a precipitating infection and DKA develops because of errors in self-management. In young patients with recurrent episodes of DKA, up to 20% may have psychological problems complicated by eating disorders.

#### Pathogenesis

A clear understanding of the biochemical basis and pathophysiology of DKA is essential for its efficient treatment (see Fig. 20.7). The cardinal biochemical features are:

- hyperketaonemia (≥3.0 mmol/L) or ketonuria (more than 2+ on standard urine sticks)
- hyperglycaemia (blood glucose ≥11 mmol/L (approximately 200 mg/dL))
- metabolic acidosis (venous bicarbonate <15 mmol/L and/ or venous pH <7.3 (H+ >50 nmol/L)).

The hyperglycaemia causes a profound osmotic diuresis leading to dehydration and electrolyte loss, particularly of...
sodium and potassium. Potassium loss is exacerbated by secondary hyperaldosteronism as a result of reduced renal perfusion. Ketosis stems from insulin deficiency, exacerbated by elevated catecholamines and other stress hormones, leading to unrestrained lipolysis and supply of FFAs for hepatic ketogenesis. When this exceeds the capacity to metabolise acidic ketones, these accumulate in blood. The resulting metabolic acidosis forces hydrogen ions into cells, displacing potassium ions.

The average loss of fluid and electrolytes in moderately severe DKA in an adult is shown in Box 20.13. About half the deficit of total body water is derived from the intracellular compartment and occurs comparatively early in the development of acidosis with relatively few clinical features; the remainder represents loss of extracellular fluid sustained largely in the later stages, when marked contraction of extracellular fluid volume occurs, with haemoconcentration, a decreased blood volume, and finally a fall in blood pressure with associated renal ischaemia and oliguria.

Every patient in DKA is potassium-depleted but the plasma concentration of potassium gives very little indication of the total body deficit. Plasma potassium may even be raised initially due to disproportionate loss of water, catabolism of protein and glycogen, and displacement of potassium from the intracellular compartment by H+ ions. However, soon after treatment is started, there is likely to be a precipitous fall in the plasma potassium due to dilution of extracellular potassium by administration of intravenous fluids, the movement of potassium into cells induced by insulin, and the continuing renal loss of potassium.

The magnitude of the hyperglycaemia does not correlate with the severity of the metabolic acidosis; moderate elevation of blood glucose may be associated with life-threatening ketoadisis. Type 1 diabetes in pregnancy is one situation where DKA can occur with blood glucose levels that are not especially high. Conversely, in other situations, hyperglycaemia predominates and acidosis is minimal, with patients presenting in a hyperosmolar state (p. 738).

Clinical assessment

The clinical features of ketoacidosis are listed in Box 20.14. In the fulminating case, the striking features are those of salt and water depletion, with loss of skin turgor, furred tongue and cracked lips, tachycardia, hypotension and reduced intra-ocular pressure. Breathing may be deep and sighing (Kussmaul’s sign), the breath is usually fetid, and the sickly-sweet smell of acetone may be apparent. Mental apathy, delirium or a reduced conscious level may be present, although coma is uncommon. Indeed, a patient with dangerous ketoacidosis requiring urgent treatment may walk into the consulting room. For this reason, the term ‘diabetic ketoacidosis’ is to be preferred to ‘diabetic coma’, which implies that there is no urgency until unconsciousness supervenes. In fact, it is imperative that energetic treatment is started at the earliest possible stage.

Abdominal pain is sometimes a feature of DKA, particularly in children, and vomiting is common. Serum amylase may be elevated but rarely indicates coexisting pancreatitis. In infected patients, pyrexia may not be present initially because of vasodilatation secondary to acidosis.

Investigations

The following investigations are important but should not delay the institution of intravenous fluid and insulin replacement:

- **Venous blood:** for urea and electrolytes, glucose, bicarbonate and acid–base status (venous blood can be used in portable and fixed blood gas analysers, and differences between venous and arterial pH and bicarbonate are minor).
- **Urine or blood analysis for ketones** (p. 726).
- **Electrocardiogram (ECG).**
- **Infection screen:** full blood count, blood and urine culture, C-reactive protein, chest X-ray. Although leucocytosis invariably occurs in DKA, this represents a stress response and does not necessarily indicate infection.

Assessment of severity

The presence of one or more of the features listed in Box 20.15 is indicative of severe DKA.

Management

DKA is a medical emergency that should be treated in hospital, preferably in a high-dependency area. If available, the diabetes specialist team should be involved. Regular clinical and biochemical review is essential, particularly during the first 24 hours of treatment. Guidelines for the management of DKA are shown in Box 20.16. Early specialist involvement is recommended for high-risk groups such as older people, young adults (18–25 years), pregnant women, and those with heart or kidney failure or other serious comorbidities.
**20.16 Emergency management of diabetic ketoacidosis**

**Time: 0–60 mins**
- Establish IV access, assess patient and perform initial investigations
- Commence 0.9% sodium chloride:
  - If systolic BP >90 mmHg, give 1 L over 60 mins
  - If systolic BP <90 mmHg, give 500 mL over 10–15 mins, then re-assess; if BP remains <90 mmHg, repeat and seek senior review
- Commence insulin treatment:
  - 50 U human soluble insulin in 50 mL 0.9% sodium chloride infused intravenously at 0.1 U/kg body weight/hr
  - Continue with SC basal insulin analogue if usually taken by patient
- Perform further investigations: see text
- Establish monitoring schedule:
  - Hourly capillary blood glucose and ketone testing
  - Venous bicarbonate and potassium after 1 and 2 hrs, then every 2 hrs for first 6 hrs
  - Plasma electrolytes every 4 hrs
  - Clinical monitoring of O₂ saturation, pulse, BP, respiratory rate and urine output every hour
- Treat any precipitating cause

**Time: 60 mins to 6 hrs**
- IV infusion of 0.9% sodium chloride with potassium chloride added as indicated below:
  - 1 L over 2 hrs
  - 1 L over 2 hrs
  - 1 L over 4 hrs
  - 1 L over 4 hrs
  - 1 L over 6 hrs
- Add 10% glucose 125 mL/hr IV when glucose <14 mmol/L (252 mg/dL)
- Be more cautious with fluid replacement in older or young people, pregnant patients and those with renal or heart failure; if plasma sodium is >155 mmol/L, 0.45% sodium chloride may be used

**Time: 6–12 hrs**
- Add potassium chloride infusion:
  - Adjust potassium chloride infusion:
    | Plasma potassium (mmol/L) | Potassium replacement (mmol/L of infusion) |
    |---------------------------|--------------------------------------------|
    | >5.5                      | Nil                                        |
    | 3.5–5.5                   | 40                                         |
    | <3.5                      | Senior review – additional potassium required |
- Clinical status, glucose, ketoaemia and acidosis should be improving; request senior review if not
- Continue IV fluid replacement
- Continue insulin administration
- Assess for complications of treatment (fluid overload, cerebral oedema)
- Avoid hypoglycaemia

**Time: 12–24 hrs**
- By 24 hrs, ketoaemia and acidosis should have resolved (blood ketones <0.3 mmol/L, venous bicarbonate >18 mmol/L)
- If patient is not eating and drinking:
  - Continue IV insulin infusion at lower rate of 2–3 U/hr
  - Continue IV fluid replacement and biochemical monitoring
- If ketoacidosis has resolved and patient is able to eat and drink:
  - Re-initiate SC insulin with advice from diabetes team; do not discontinue IV insulin until 30 mins after SC short-acting insulin injection

**Additional procedures**
- Consider urinary catheterisation if anuric after 3 hrs or incontinent
- Insert nasogastric tube if obtunded or there is persistent vomiting
- Insert central venous line if cardiovascular system is compromised, to allow fluid replacement to be adjusted accurately; also consider in older patients, pregnant women, renal or cardiac failure, other serious comorbidities and severe DKA
- Measure arterial blood gases; repeat chest X-ray if O₂ saturation <92%
- Institute ECG monitoring in severe cases
- Give thromboprophylaxis with low-molecular-weight heparin

---

**Insulin**

A fixed-rate intravenous insulin infusion of 0.1 U/kg body weight/hr is recommended (Box 20.16). Exceptionally, if intravenous administration is not feasible, soluble insulin can be given by intramuscular injection (loading dose of 10–20 U, followed by 5 U hourly), or a fast-acting insulin analogue can be given hourly by subcutaneous injection (initially 0.3 U/kg body weight, then 0.1 U/kg hourly). The blood glucose concentration should fall by 3–6 mmol/L (approximately 55–110 mg/dL) per hour, or blood ketone concentrations fall by at least 0.5 mmol/L/hr. A more rapid decrease in blood glucose should be avoided, as this might precipitate hypoglycaemia and the serious complication of cerebral oedema, particularly in children. Failure of blood glucose to fall within 1 hour of commencing insulin infusion should lead to a re-assessment of insulin dose. Ketosis, dehydrating, acidemia, infection and stress combine to produce severe insulin resistance in some cases, but most will respond to a low-dose insulin regimen. When the blood glucose has fallen, 10% dextrose infusion is introduced and insulin infusion continued to encourage glucose uptake into cells and restoration of normal metabolism. In recent years, it has also become increasingly common to continue with the use of long-acting insulin analogues administered subcutaneously during the initial management of DKA; this provides background insulin for when the intravenous insulin is discontinued, to reduce the risk of in-hospital DKA.

Restoration of the usual insulin regimen, by subcutaneous injection, should not be instituted until the patient is both biochemically stable and able to eat and drink normally.

**Fluid replacement**

In adults, rapid fluid replacement in the first few hours is usually recommended (Box 20.16). Caution is advised in children and young adults because of the risk of cerebral oedema. Most guidelines favour correction of the extracellular fluid deficit with isotonic saline (0.9% sodium chloride). If the plasma sodium is greater than 155 mmol/L, 0.45% saline may be used initially. Introduction of 10% glucose is recommended when the blood glucose falls below 14 mmol/L (252 mg/dL). The 0.9% saline infusion should be continued to correct circulating volume so both glucose and saline infusions are used concurrently.

---

**Adapted from Joint British Diabetes Societies Inpatient Care Group. The Management of Diabetic Ketoacidosis in Adults, 2nd edn; September 2013; abcd.care.**
Potassium

Careful monitoring of potassium is essential to the management of DKA because both hypo- and hyperkalaemia can occur and are potentially life-threatening. Potassium replacement is not usually recommended with the initial litre of fluid because pre-renal failure may be present secondary to dehydration. Treatment with 0.9% sodium chloride with potassium chloride 40 mmol/L is recommended if the serum potassium is below 5.5 mmol/L and the patient is passing urine (Box 20.16). If the potassium falls below 3.5 mmol/L, the potassium replacement regimen needs to be reviewed. Aim to maintain potassium between 4.0 and 5.5 mmol/L. Cardiac rhythm should be monitored in severe DKA because of the risk of electrolyte-induced cardiac arrhythmia.

Bicarbonate

Adequate fluid and insulin replacement should resolve the acidosis. The use of intravenous bicarbonate therapy is not recommended. Acidosis may reflect an adaptive response, improving oxygen delivery to the tissues, and so excessive bicarbonate may induce a paradoxical increase in cerebrospinal fluid acidosis and has been implicated in the pathogenesis of cerebral oedema in children and young adults.

Phosphate

There is no evidence of benefit with phosphate replacement unless low levels are detected in the presence of respiratory or muscle weakness.

Ongoing management

Where possible, refer the patient to the diabetes specialist team within 24 hours of admission. It is important to review the precipitating factors that led to DKA, glycaemic control and insulin injection technique, as well as to discuss prevention of recurrence and to provide blood ketone meters where available. There is a significant mortality associated with recurrent DKA and so early educational assessment and treatment review are critical.

Hyperglycaemic hyperosmolar state

Hyperglycaemic hyperosmolar state (HHS) is a medical emergency that is different from DKA and so treatment requires a different approach. There is no precise definition of HHS but it is characterised by hypovolaemia, severe hyperglycaemia (>30 mmol/L (600 mg/dL)) and hyperosmolality (serum osmolality >320 mOsmol/kg), without significant ketonaemia (<3 mmol/L) or acidosis (pH >7.3 (H+ <50 mmol/L), bicarbonate >15 mmol/L).

As with DKA, there is glycosuria, leading to an osmotic diuresis with loss of water, sodium, potassium and other electrolytes. However, in HHS, hyperglycaemia usually develops over a longer period (a few days to weeks), causing more profound hyperglycaemia and dehydration (fluid loss may be 10–12 L in a person weighing 100 kg). The reason that patients with HHS do not develop significant ketoadiogensis is unclear, although it has been speculated that insulin levels may be too low to stimulate glucose uptake in insulin-sensitive tissues, but are still sufficient to prevent lipolysis and subsequent ketogenesis. A mixed picture of HHS and DKA can occur.

Although typically occurring in older patients, HHS is increasingly seen in younger adults. Common precipitating factors include infection, myocardial infarction, cerebrovascular events or drug therapy (e.g. glucocorticoids). Poor prognostic signs include hypothermia, hypotension (systolic blood pressure <90 mmHg), tachy- or bradycardia, severe hypernatraemia (sodium >160 mmol/L), serum osmolality >360 mOsmol/kg, and the presence of other serious comorbidities. Mortality rates are higher than in DKA – up to 20% in the USA – reflecting the age and frailty of the population and the more frequent presence of comorbidities.

The principles of therapy are shown in Box 20.17. The aims to are normalise osmolality, replace fluid and electrolyte losses, and normalise blood glucose, at the same time as preventing complications such as arterial or venous thrombosis, cerebral oedema and central pontine demyelination (Ch. 14). Comorbidities also need to be taken into account; for example, rapid fluid replacement may precipitate cardiac failure in patients with coronary artery disease. Historically, management of HHS has followed DKA guidelines, but increasing recognition of the differences between HHS and DKA has led to new approaches in HHS. In particular, rapid shifts in osmolality should be avoided through more measured fluid replacement regimens that are guided by serial calculations of serum osmolality. Key recommendations are that 0.9% sodium chloride solution alone is used for initial treatment, and that insulin is introduced only when the rate of fall in blood glucose has plateaued.

If osmolality cannot be measured frequently, osmolarity can be calculated as follows and used as a surrogate (based on plasma values in mmol/L):

\[
\text{Plasma osmolality} = 2(\text{[Na}^+\text{]} + \text{[glucose]} + \text{[urea]})
\]

The normal value is 280–296 mOsmol/L and consciousness is impaired when it is high (>340 mOsmol/L), as commonly occurs in HHS. A limitation of this approach is that hyperglycaemia, by increasing serum osmolality, causes the movement of water out of cells, therefore reducing measured Na+ levels by dilution. In hyperglycaemic patients, the corrected [Na+] should be taken into account. This is calculated by adding 1.6 mmol/L to the measured [Na+] for every 5.55 mmol/L (100 mg/dL) increment of serum glucose above normal.

Hypoglycaemia

Hypoglycaemia is uncommon in people without diabetes but relatively frequent in people with diabetes, mainly due to insulin therapy, and less frequently to use of oral insulin secretagogues such as sulphonylurea drugs, and rarely with other antidiabetic drugs. In people with diabetes, hypoglycaemia is defined as a blood glucose of less than 3.9 mmol/L (70 mg/dL). Severe hypoglycaemia – the need for external assistance to provide glucose, glucagon or other corrective action actively – is greatly feared by people with diabetes and has a major impact on their willingness and ability to achieve target glucose levels. When hypoglycaemia develops in non-diabetic people, it is called ‘spontaneous’ hypoglycaemia; its definition, causes and investigation are described on page 676.

The critical importance of glucose as a fuel source for the brain means that, in health, a number of mechanisms are in place to ensure that glucose homeostasis is maintained. If blood glucose falls, three primary physiological defence mechanisms operate:

- endogenous insulin release from pancreatic β cells is suppressed
- release of glucagon from pancreatic α cells is increased
- the autonomic nervous system is activated, with release of catecholamines both systemically and within the tissues.

Acidosis may reflect an adaptive response, improving oxygen delivery to the tissues, and so excessive bicarbonate may induce a paradoxical increase in cerebrospinal fluid acidosis and has been implicated in the pathogenesis of cerebral oedema in children and young adults.

Where possible, refer the patient to the diabetes specialist team within 24 hours of admission. It is important to review the precipitating factors that led to DKA, glycaemic control and insulin injection technique, as well as to discuss prevention of recurrence and to provide blood ketone meters where available. There is a significant mortality associated with recurrent DKA and so early educational assessment and treatment review are critical.
In addition, stress hormones, such as cortisol and growth hormone, are increased in the blood. These actions reduce whole-body glucose uptake and increase hepatic glucose production, maintaining a glucose supply to the brain. People with type 1 diabetes cannot regulate insulin once it is injected subcutaneously, and so it continues to act, despite the development of hypoglycaemia. In addition, within 5 years of diagnosis, most patients will have lost their ability to release insulin, and so insulin or other products of the \( \alpha \)-cell regulation. These two primary defects mean that hypoglycaemia occurs much more frequently in people with type 1 diabetes than in people with type 2 diabetes.

**Clinical assessment**

Symptoms of hypoglycaemia (Box 20.18) comprise two main groups: those related to acute activation of the autonomic nervous system and those secondary to glucose deprivation of the brain (neuroglycopenia). Symptoms of hypoglycaemia are idiosyncratic, differing with age and duration of diabetes, and also depending on the circumstances in which hypoglycaemia occurs. Hypoglycaemia also affects mood, inducing a state of increased tension and low energy. Learning to recognise the early onset of hypoglycaemia is an important aspect of the education of people with diabetes treated with insulin.

N.B. Symptoms differ with age; children exhibit behavioural changes (such as naughtiness or irritability), while older people experience more prominent neurological symptoms (such as visual disturbance and ataxia).

Circumstances of hypoglycaemia

Risk factors and causes of hypoglycaemia in patients taking insulin or sulphonylurea drugs are listed in Box 20.19. Severe hypoglycaemia can have serious morbidity (e.g. convulsions, coma, focal neurological lesions) and has a mortality of up to...
Exercise-induced hypoglycaemia occurs in people with well-controlled, insulin-treated diabetes because of hyperinsulinaemia. Suppression of endogenous insulin secretion to allow increased hepatic glucose production to meet the increased metabolic demand is key to the normal physiological response to exercise. In insulin-treated diabetes, insulin levels may actually increase with exercise because of improved blood flow at the site of injection, and this increases the risk of hypoglycaemia. This means that both insulin and muscle contraction will increase glucose uptake, causing a fall in blood glucose. This occurs most commonly with prolonged and/or aerobic exercise. In addition, the ‘double hit’ of hypoglycaemia with exercise reflects the additional increased risk of nocturnal hypoglycaemia that can occur after exercise, possibly as a result of glycogen depletion. In contrast, high-intensity exercise because of the marked stimulation to adrenaline (epinephrine) production may actually cause blood glucose to rise significantly. Education is key to preventing exercise-induced hypoglycaemia.

Hypoglycaemia may also occur within the hospital setting. This may result from errors in insulin dose or type of insulin prescribed, infusion of IV insulin without glucose, changes in meal timings or content and failure to provide usual snacks, reduced carbohydrate intake because of vomiting or reduced appetite, or factors related to the hospital admission, e.g. concurrent illness or discontinuation of long-term glucocorticoid therapy.

Awareness of hypoglycaemia

For most individuals, the glucose level (threshold) at which they first become aware of hypoglycaemia is not constant but varies according to the circumstances in which hypoglycaemia arises (e.g. during the night or during exercise). In addition, with longer duration of disease, and particularly in response to frequent hypoglycaemia, the threshold for generation of symptomatic responses to hypoglycaemia shifts to a lower glucose concentration. This cerebral adaptation has a similar effect on the counter-regulatory hormonal response to hypoglycaemia. Taken together, this means that individuals with type 1 diabetes may have reduced (impaired) awareness of hypoglycaemia. Symptoms can be experienced less intensely, or even be absent, despite blood glucose concentrations below 3.0 mmol/L (55 mg/dL). Such individuals are at an especially high risk of severe hypoglycaemia. The prevalence of impaired awareness of hypoglycaemia increases with time; overall, it affects around 20–25% of people with type 1 diabetes and under 10% with insulin-treated type 2 diabetes.

Management

Acute treatment of hypoglycaemia

Treatment of hypoglycaemia depends on its severity and on whether the patient is conscious and able to swallow (Box 20.20). Oral carbohydrate usually suffices if hypoglycaemia is recognised early. If parenteral therapy is required, then as soon as the patient is able to swallow, glucose should be given orally. Full recovery may not occur immediately and reversal of cognitive impairment may not be complete until 60 minutes after normoglycaemia is restored. When hypoglycaemia has occurred in a patient treated with a long- or intermediate-acting insulin or a long-acting sulphonylurea, such as gliclazide, the possibility of recurrence should be anticipated; to prevent this, infusion of 10% dextrose, titrated to the patient’s blood glucose, or provision of additional carbohydrate may be necessary. If the patient fails to regain consciousness after blood glucose is restored to normal, then cerebral oedema and other causes of impaired consciousness – such as alcohol intoxication, a post-ictal state or cerebral haemorrhage – should be considered. Cerebral oedema has a high mortality and morbidity.

Following recovery, it is important to try to identify a cause and make appropriate adjustments to the patient’s therapy. Unless the reason for a hypoglycaemic episode is clear, the patient should reduce the next dose of insulin by 10–20% and seek medical advice about further adjustments in dose.

The management of self-poisoning with oral antidiabetic agents is described on page 141.

Prevention of hypoglycaemia

Patient education is fundamental to the prevention of hypoglycaemia. Risk factors for, and treatment of, hypoglycaemia should be discussed. The importance of regular blood glucose monitoring and the need to have glucose (and glucagon) readily available should be stressed. A review of insulin and carbohydrate intake

including employment, driving (see Box 20.24), travel, sport and disruptive and impinges on many aspects of the patient’s life, induced cardiac arrhythmia. Severe hypoglycaemia is very 4% in insulin-treated patients. Rarely, sudden death during sleep occurs in otherwise healthy young patients with type 1 diabetes (‘dead-in-bed syndrome’) and may result from hypoglycaemia-induced cardiac arrhythmia. Severe hypoglycaemia is very disruptive and impinges on many aspects of the patient’s life, including employment, driving (see Box 20.24), travel, sport and personal relationships.

Nocturnal hypoglycaemia in patients with type 1 diabetes is common but often undetected, as hypoglycaemia does not usually waken a person from sleep. Patients may describe poor quality of sleep, morning headaches and vivid dreams or nightmares, or a partner may observe profuse sweating, restlessness, twitching or even seizures. The only reliable way to identify this problem is to measure blood glucose during the night. High glucose levels in the morning are not, as commonly perceived, an indicator of nocturnal hypoglycaemia.

Exercise-induced hypoglycaemia may occur in people with well-controlled, insulin-treated diabetes because of hyperinsulinaemia. Suppression of endogenous insulin secretion to allow increased hepatic glucose production to meet the increased metabolic demand is key to the normal physiological response to exercise. In insulin-treated diabetes, insulin levels may actually increase with exercise because of improved blood flow at the site of injection, and this increases the risk of hypoglycaemia. This means that both insulin and muscle contraction will increase glucose uptake, causing a fall in blood glucose. This occurs most commonly with prolonged and/or aerobic exercise. In addition, the ‘double hit’ of hypoglycaemia with exercise reflects the additional increased risk of nocturnal hypoglycaemia that can occur after exercise, possibly as a result of glycogen depletion. In contrast, high-intensity exercise because of the marked stimulation to adrenaline (epinephrine) production may actually cause blood glucose to rise significantly. The importance of regular blood glucose monitoring and the need to have glucose (and glucagon) readily available should be stressed. A review of insulin and carbohydrate intake

Medical issues

- Rapid improvement in and/or strict glycaemic control
- Previous severe hypoglycaemia
- Impaired awareness of hypoglycaemia
- Long-duration type 1 diabetes
- Duration of insulin therapy in type 2 diabetes
- Lipohypertrophy at injection sites causing variable insulin absorption
- Severe hepatic dysfunction
- Impaired renal function
- Inadequate treatment of previous hypoglycaemia
- Terminal illness
- Bariatric surgery involving bowel resection
- Unrecognised other endocrine disorder, e.g. Addison’s disease

Reduced carbohydrate intake

- Gastroparesis due to autonomic neuropathy causing variable carbohydrate absorption
- Malabsorption, e.g. coeliac disease
- Eating disorder

Lifestyle issues

- Exercise
- Irregular lifestyle
- Increasing age
- Alcohol
- Early pregnancy

Breastfeeding
- No or inadequate glucose monitoring
- Factitious (deliberately induced)
management during exercise is particularly useful. Advice for this, the evening dose of depot intermediate-acting insulin should be deferred until bedtime (after 2300 hrs), shifting its peak action period to 0500–0700 hrs. It is also a sensible precaution for patients to measure their blood glucose before they retire to bed and to have a carbohydrate snack if the reading is less than 6.0 mmol/L (approximately 110 mg/dL).

### Management of diabetes

The aims are to improve symptoms of hyperglycaemia and minimise the risks of long-term microvascular and macrovascular complications. Treatment methods for diabetes include dietary/lifestyle modification, oral antidiabetic drugs and injected therapies. Initial investigation and management is outlined in Figure 20.10. In patients with suspected type 1 diabetes, urgent treatment with insulin is required and prompt referral to a specialist is usually needed. In patients with suspected type 2 diabetes, the first approach to management involves advice about dietary and lifestyle modification. Oral antidiabetic drugs are usually added in those who do not achieve glycaemic targets, or who have symptomatic hyperglycaemia at diagnosis and a high HbA1c. However, the guidelines in some countries are to introduce medication immediately on diagnosis of diabetes without waiting to assess the impact of diet and lifestyle changes. Patients with type 2 diabetes who present with marked symptomatic hyperglycaemia or DKA will require initial management with insulin treatment.

For most people, types 1 and 2 diabetes are chronic conditions that will impact on their day-to-day activities and require sustained changes to lifestyle. Education is key to achieving and maintaining a healthy lifestyle and to managing diabetes. Early educational intervention at diagnosis and repeated education are essential if these goals are to be successfully achieved. Management of people with diabetes should be individualised where possible, taking into account personal and cultural beliefs, individual circumstances, comorbidities and other factors.

Diabetes is a complex disorder that progresses in severity with time, so people with diabetes should be seen at regular intervals for the remainder of their lives, either at a specialist diabetic clinic or in primary care where facilities are available and staff are trained in diabetes care. A checklist for follow-up visits is given in Box 20.22. The frequency of visits is variable, ranging from weekly during pregnancy to annually in the case of patients with well-controlled type 2 diabetes.

In parallel with treatment of hyperglycaemia, other risk factors for complications of diabetes need to be addressed, including treatment of hypertension (p. 510) and dyslipidaemia (p. 373), and advice on smoking cessation (p. 94).
### Self-assessment of glycaemic control

In people with type 2 diabetes, there is not usually a need for regular self-assessment of blood glucose, unless they are treated with insulin, or at risk of hypoglycaemia while taking sulphonylureas. Blood glucose testing can be used for self-education (i.e. demonstrating how different food and exercise regimes affect blood glucose) and may be useful in acute illness. Blood glucose targets vary according to individual circumstances but, in general, fasting glucose levels of 5–7 mmol/L (90–126 mg/dL) and 2-hour post-meal values of 4–8 mmol/L (72–144 mg/dL) represent optimal control.

Insulin-treated patients should be taught how to monitor their own blood glucose using capillary blood glucose meters. Immediate knowledge of blood glucose levels can be used by patients to guide their insulin dosing and to manage exercise and illness. This can be supplemented with blood testing for ketones when blood glucose is high and/or during intercurrent illness. More recently, continuous glucose monitoring systems (CGMS) have been developed that allow for a more detailed examination of daily glucose profiles. These can be used continuously as part of day-to-day diabetes management or intermittently as an educational tool.

Urine testing for glucose is not recommended because variability in renal threshold means that some patients with inadequate glycaemic control will not find glucose in their urine.

### Therapeutic goals

The target HbA1c depends on the individual patient. Early on in diabetes (i.e. patients managed by diet or one or two oral agents), a target of 48 mmol/mol or less may be appropriate. However, a higher target of 58 mmol/mol may be more appropriate in older patients with pre-existing cardiovascular disease, or those treated with insulin and therefore at risk of hypoglycaemia. In general, the benefits of lower target HbA1c (primarily, a lower risk of microvascular disease) need to be weighed against any increased risks (primarily, hypoglycaemia in insulin-treated patients). Type 2 diabetes is usually a progressive condition...
alcohol consumption, should not be underestimated in improving glycaemic control for people with both type 1 and type 2 diabetes. Many people find this difficult to sustain and constant reinforcement of the benefits of lifestyle change will usually be required. Patients should be encouraged to stop smoking.

**Healthy eating**

All people with diabetes need to pay special attention to their diet (Box 20.23; see also p. 694). They should have access to a dietitian at diagnosis, at review and at times of treatment change. Nutritional advice should be tailored to individuals and take account of their age, lifestyle, culture and personal circumstances. Structured education programmes are available for both common types of diabetes and, if possible, a clear referral mechanism for diabetes education should be in place.

Between 80% and 90% of people with type 2 diabetes are overweight and so the majority require dietary advice for achieving weight loss, to include caloric restriction. There is, however, limited evidence for the ideal macronutrient composition of the diet in type 2 diabetes. In general, high fat intake (especially saturated fats) is associated with a raised HbA1c, but it is unclear how the type and amount of fat influence post-prandial glucose control. Reduction of caloric intake and weight loss should be the major goals. Some evidence for the Mediterranean diet, low-carbohydrate diets and meal replacements is emerging. Whichever approach is taken, weight loss in overweight and obese individuals with diabetes markedly improves glycaemic control and slows diabetes progression.

**Carbohydrate**

While it is recognised that the total amount of carbohydrate is the major determinant of post-prandial glucose (p. 694), there is little evidence to support specific strategies for carbohydrate intake in type 2 diabetes or to identify the ideal amount of carbohydrate in their diet. Current UK government Food Standards Agency recommendations are that the total carbohydrate intake should be no more than 50% of energy, and of this non-milk extrinsic sugars (e.g. table sugar, honey,

**Blood pressure**

- Individualised target of 130–140/70–80 mmHg, depending on risk factors and presence of nephropathy

**Biochemistry**

- Renal, liver and thyroid function
- Lipid profile and estimated 10-year cardiovascular risk to guide need for lipid-lowering therapy

**Glycaemic control**

- Glycated haemoglobin (HbA1c); individualised target between 48 and 58 mmol/mol
- Lipid profile
- Total cholesterol levels
- Triglycerides
- HDL cholesterol

**Hypoglycaemic episodes**

- Number and cause of severe (requiring assistance for treatment) events and frequency of mild (self-treated) episodes and biochemical hypoglycaemia
- Awareness of hypoglycaemia
- Driving advice

**Assessment of injection sites if insulin-treated**

**Eye examination**

- Visual acuities (near and distance)
- Ophthalmoscopy (with pupils dilated) or digital photography

**Examination of lower limbs and feet**

- Assessment of foot risk

(Fig. 20.11) unless there are major diet and lifestyle changes, so that there is usually a need to increase diabetes medication over time to achieve the individualised target HbA1c.

In people with type 2 diabetes, treatment of coexisting hypertension and dyslipidaemia is usually required. This can be decided by assessing absolute risk of a cardiovascular disease event (p. 510) and adjusting targets to individual circumstances. The target for blood pressure is usually below 140/80 mmHg, although some guidelines suggest 130/80 mmHg. For lipid-lowering, there is a reduction in cardiovascular risk even with normal cholesterol levels, but statin therapy is usually recommended when the 10-year cardiovascular event risk is at least 20%. As a rule, anyone with type 2 diabetes who is over the age of 40 years should receive a statin, irrespective of baseline cholesterol levels. Some guidelines do not propose a target level once the patient is started on a statin but others suggest a total cholesterol of less than 4.0 mmol/L (approximately 150 mg/dL) and an LDL cholesterol of less than 2.0 mmol/L (approximately 75 mg/dL). Similar targets are appropriate in type 1 diabetes, although there is a shortage of data from clinical trials.
glucose and fructose sugars) should not be more than 11%. Low glycaemic index (GI) diets have, in some short-term trials, been shown to improve HbA1c, but the literature concerning GI and glycaemic control is mixed. The GI of a carbohydrate-containing food is a measure of the change in blood glucose following its ingestion relative to the rise in blood glucose observed following a liquid OGTT. Different foods can be ranked by their effect on post-prandial glycaemia. Low-Gl foods, such as starchy foods (e.g. basmati rice, spaghetti, porridge, noodles, granary bread, and beans and lentils), may reduce post-prandial glucose excursions. However, different methods of food processing and preparation can influence the GI of foods, and this may limit their benefit.

Low-carbohydrate diets may lead to significant reductions in body weight and improved glycaemic control in the short term, although high dropout rates and poor adherence have limited widespread application of this approach. Increased consumption of whole grains has not been shown to improve glycaemic control.

**Fat**

There is limited evidence on the ideal fat content in the diet of people with diabetes. Current UK government Food Standards Agency recommendations are that intake of total fat should be not more than 35% of energy intake, of which not more than 11% should consist of polyunsaturated fats. The type of fatty acids consumed may be more important when looking at glycaemic targets and risk of cardiovascular disease. Mediterranean diets rich in monounsaturated fats appear more beneficial (Box 20.23). The influence of dietary fats on plasma lipid profile and cardiovascular disease is discussed on page 697.

**Salt**

People with diabetes should follow the advice given to the general population: namely, adults should limit their sodium intake to no more than 6 g daily.

---

### Weight management

In patients with diabetes, weight management is important, as a high percentage of people with type 2 diabetes are overweight or obese, and many antidiabetic drugs, including insulin, encourage weight gain. Obesity, particularly central obesity with increased waist circumference, also predicts insulin resistance and cardiovascular risk.

Management of obesity is described on page 700. Weight loss can be achieved through a reduction in energy intake and an increase in energy expenditure through physical activity. Lifestyle interventions or pharmacotherapy for obesity, when associated with weight reduction, have beneficial effects on HbA1c, but long-term benefits in terms of glycaemic control and microvascular disease have not been adequately assessed. More recently, bariatric surgery (p. 703) has been shown to induce marked weight loss in obese individuals with type 2 diabetes and this is often associated with significant improvements in HbA1c and withdrawal of or reduction in diabetes medications.

### Exercise

All patients with diabetes should be advised to achieve a significant level of physical activity and to maintain this in the long term. This can include activities such as walking, gardening, swimming or cycling. Supervised and structured exercise programmes may be of particular benefit in type 2 diabetes. Various guidelines exist for physical activity in the general population. The American Diabetes Association recommends that all adults with diabetes are encouraged to reduce sedentary time, and suggest that adults over 18 years of age should do either 150 minutes per week of moderate-intensity exercise or 75 minutes per week of vigorous-intensity exercise, or a combination thereof. Muscle-strengthening (resistance) exercise is recommended on 2 or more days of the week. Adults over 65 years or those with disabilities should follow the recommended guidelines if possible or be as physically active as they are able. Recent evidence also indicates that extended sedentary time (>90 mins) should be avoided.

People with type 1 diabetes appear to exercise less frequently than the general population, perhaps because of perceived concerns about hypoglycaemia and difficulties in insulin management around exercise. However, the health benefits of exercise are equally important in type 1 diabetes, so this should be addressed in the clinic and specialist advice sought on insulin and carbohydrate management before, during and after exercise.

### Alcohol

Alcohol is recognised as having both beneficial and harmful effects on cardiovascular disease and this also appears to apply in patients with diabetes. Alcohol can therefore be taken in moderation in diabetes, with the aim of keeping within national guidelines relating to recommendations for people without diabetes (e.g. in the UK, the weekly recommended maximum is 14 units for women and men). However, alcohol can reduce hypoglycaemia awareness and, by suppressing gluconeogenesis, increase hypoglycaemia risk. The latter occurs when individuals are in the fasted state and so people with diabetes who drink should be advised to eat at the same time. In addition, all patients with diabetes should be made aware of the high calorie...
content of some alcohols and the implications for body weight management, which are often overlooked.

## Driving

European legislation on driving has had a major impact on people with diabetes. Legislation will vary from country to country and so individuals should contact their nurse or doctor to find out if their treatment means they need to inform the licensing authority (Box 20.24). To drive a car or ride a motorcycle in the UK, people with diabetes who take insulin replacement therapy must notify the Driver and Vehicle Licensing Agency (DVLA). They must have adequate awareness of hypoglycaemia, have had no more than one episode of severe hypoglycaemia in the preceding 12 months, meet the standards for visual acuity and visual fields, and not be regarded as a likely risk to the public while driving. In addition, blood glucose testing is required to be performed no more than 2 hours before the start of a journey and every 2 hours while driving. Blood glucose levels should be over 5 mmol/L (90 mg/dL) before driving; if they are below 4.0 mmol/L (72 mg/dL) or there are symptoms of hypoglycaemia, the person should not drive. Legislative requirements for people on insulin therapy who drive larger vehicles such as buses or lorries require, in addition, an annual examination by a diabetes specialist, along with review of 3 months of glucose meter readings. Legislation differs between countries and patients and health-care specialists need to be aware of current requirements.

### 20.24 Diabetes and driving

- Licensing regulations vary considerably between countries. In the UK, diabetes requiring insulin therapy or any complication that could affect driving should be declared to the Driver and Vehicle Licensing Agency; ordinary driving licences are ‘period-restricted’ for insulin-treated drivers; and vocational licences (large goods vehicles and public service vehicles) may be granted but require very strict criteria to be met.
- The main risk to driving performance is hypoglycaemia. Visual impairment and other complications may occasionally cause problems.
- Insulin-treated diabetic drivers should:
  - Check blood glucose before driving and 2-hourly during long journeys.
  - Keep an accessible supply of fast-acting carbohydrate in the vehicle.
  - Take regular snacks or meals during long journeys.
  - Stop driving if hypoglycaemia develops.
  - Refrain from driving until at least 45 mins after treatment of hypoglycaemia (delayed recovery of cognitive function).
  - Carry identification in case of injury.

## Ramadan

The Qur’an requires Muslims to fast during the month of Ramadan from sunrise to sunset. While people with diabetes are a recognised exception to this and are not required to fast, many will choose to do so. In this context, patient education, regular glucose monitoring and adjustment of treatment regimens are essential and should occur weeks prior to Ramadan. The highest risk of hypoglycaemia is in patients treated with sulphphonylureas and insulin (particularly older people or those with renal failure); such individuals need careful blood glucose monitoring and, if necessary their treatment regimens may need to be adjusted (Box 20.25). Diabetes therapies that do not cause hypoglycaemia may prove safest during Ramadan if glycaemic control permits. DPP-4 inhibitors or GLP-1 receptor agonists may be especially useful because their effect on insulin secretion is glucose-dependent.

### 20.25 Recommendations for management of diabetes during Ramadan

- Monitor blood glucose: depending on treatment regimen, glucose levels should be checked daily or several times a day. Patients treated with insulin and insulin secretagogues should measure glucose before, during and after fasting (2–4 times daily).
- Consult diabetes team for medication adjustment at least 1 month prior to Ramadan. Treatment should be evaluated and modified according to risk of hypoglycaemia. Avoid or reduce sulphphonylureas and/or insulin daily dosage.
- Avoid skipping pre-dawn meals.
- Avoid strenuous physical activity during fasting period.
- Adjust medication dose and eat a snack in the presence of hypoglycaemia. Break the fast if there is severe or recurrent hypoglycaemia.

## Drugs to reduce hyperglycaemia

Patients whose glycaemic control deteriorates after a period of satisfactory control need their therapy to be adjusted. However, this is not a homogeneous group; it includes some patients with late-onset type 1 diabetes who develop an absolute deficiency of insulin, some with type 2 diabetes whose β-cell failure is advanced, and others who are not adhering to the recommended lifestyle changes or medication. Weight loss suggests worsening β-cell function. During continuing follow-up, the majority of patients will require combinations of antidiabetic drugs, often with additional insulin replacement, to obtain satisfactory glycaemic control.

For many years, only a few choices of drug were available for type 2 diabetes – the biguanide metformin, the sulphphonylureas and insulin. Insulin is the only treatment for type 1 diabetes, although sometimes metformin is used with insulin in type 1 diabetes. Acarbose is also available but is little used in most countries. Since the late 1990s, however, several new classes of agent have been approved for use in type 2 diabetes, with more in development. These include thiazolidinediones, dipeptidyl peptidase 4 (DPP-4) inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, and sodium and glucose transporters of sodium-glucose transporters 2 (SGLT2) inhibitors. The effects of these drugs are compared in Box 20.26. This makes for an exciting time in diabetes pharmacotherapy but exactly how, when and in what order these agents should be used remains uncertain. The older drugs are cheaper and have established benefits for reducing microvascular disease; they are therefore usually recommended as first-line therapy. Use of the newer drugs is not supported by evidence for reduction in microvascular disease (because the trials have not yet been done) and they are much more expensive, so are often reserved for later therapy after failure of metformin and sulphphonylureas. The American Diabetes Association/European Association for the Study of Diabetes (ADA/EASD) consensus...
guidelines are shown in Figure 20.10. These position metformin in the first line, and then aim to encourage choice of second-line treatment to be personalised for each patient. This personalisation is largely based on the adverse risk profile of the drug – in particular, risk of hypoglycaemia (avoid where hypoglycaemia would be a problem, e.g. in drivers of heavy goods vehicles) and weight gain. There is little evidence to guide the clinician in choosing the second- or third-line treatment, and until biomarkers are identified that predict who will respond best and/or experience the fewest side-effects with one drug rather than another, this individualisation of treatment needs to be largely empirical. A trial-and-error approach may be best: stop a drug that does not work or that causes side-effects rather than another, this individualisation of treatment needs to be largely empirical. A trial-and-error approach may be best: stop a drug that does not work or that causes side-effects and trial the next drug. At the time of writing, the ADA/EASD guidelines were already out of date; in 2015/16, the SGLT2 inhibitor empagliflozin and the GLP-1 receptor agonist liraglutide were shown to reduce adverse cardiovascular outcomes and mortality. It is likely that the guidelines will change to take these exciting results into account and we will probably see these newer, more expensive drugs used earlier in the diabetes trajectory.

(↑↑ = small reduction; DPP-4 = dipeptidyl peptidase 4; GLP-1 = glucagon-like peptide 1; SGLT2 = sodium and glucose transporter 2)

At the molecular level, metformin acts as a weak inhibitor of mitochondrial respiration, which increases intracellular adenosine monophosphate (AMP) and reduces adenosine triphosphate (ATP). This has direct effects on the flux through gluconeogenesis, and activates the intracellular energy sensor, AMP-activated protein kinase (AMPK), leading to multiple beneficial metabolic effects. However, metformin is still effective in mice lacking AMPK, and a number of AMPK-independent mechanisms have been proposed.

**Clinical use**

Metformin is a potent blood glucose-lowering treatment that is weight-neutral or causes weight loss, does not cause hypoglycaemia and has established benefits in microvascular disease. It is employed as first-line therapy in all patients who tolerate it, and its use is maintained when additional agents are added as glycaemia deteriorates (see Fig. 20.10). Metformin is usually introduced at low dose (500 mg twice daily) to minimise the risk of gastrointestinal side-effects. The usual maintenance dose is 1 g twice daily. There is a modified-release formulation of metformin, which may be better tolerated by patients with gastrointestinal side-effects. Metformin can increase susceptibility to lactic acidosis, although this is much less common than was previously thought. As metformin is cleared by the kidneys, it can accumulate in renal impairment, so the dose should be halved when estimated glomerular filtration rate (eGFR) is 30–45 mL/min/1.73 m², and it should not be used below an eGFR of 30 mL/min/1.73 m². It should be omitted temporarily during any acute illness where acute kidney injury is possible, as this greatly increases the risk of lactic acidosis; insulin treatment may be required while metformin is withheld. Its use is also contraindicated in patients with significantly impaired hepatic function and in those who drink alcohol in excess, in whom the risk of lactic acidosis is significantly increased.

**Biguanides**

Metformin is the only biguanide available. Its long-term benefits were shown in the UK Prospective Diabetes Study (UKPDS, p. 756) and it is now widely used as first-line therapy for type 2 diabetes, irrespective of body weight. It is also given as an adjunct to insulin therapy in obese patients with type 1 diabetes. Approximately 25% of patients develop mild gastrointestinal side-effects with metformin, but only 5% are unable to tolerate it even at low dose. The main side-effects are diarrhoea, abdominal cramps, bloating and nausea.

**Mechanism of action**

The mechanism of action of metformin has not been precisely defined. While classically considered an ‘insulin sensitiser’ because it lowers insulin levels, its main effects are on fasting glucose and are insulin-independent. Metformin reduces hepatic glucose production, may also increase insulin-mediated glucose uptake, and has effects on gut glucose uptake and utilisation.

**Sulphonylureas**

Sulphonylures are ‘insulin secretagogues’, i.e. they promote pancreatic β-cell insulin secretion. Similar to metformin, the long-term benefits of sulphonylures in lowering microvascular
complications of diabetes were established in the UKPDS (p. 756).

**Mechanism of action**

Sulphonylureas act by closing the pancreatic $\beta$-cell ATP-sensitive potassium ($K_{ATP}$) channel, decreasing $K^+$ efflux, which ultimately triggers insulin secretion (see Fig. 20.2C). Meglitinides (e.g. repaglinide and nateglinide) also work in this way and, although short-acting, are essentially sulphonylurea-like drugs.

**Clinical use**

Sulphonylureas are an effective therapy for lowering blood glucose and are often used as an add-on to metformin, if glycaemia is inadequately controlled on metformin alone (see Fig. 20.10). The main adverse effects of sulphonylureas are weight gain and hypoglycaemia. The weight gain is not ideal in patients with diabetes who are already overweight or obese, although sulphonylureas are effective treatments in this group. Hypoglycaemia occurs because the closure of $K_{ATP}$ channels brings about unregulated insulin secretion, even with normal or low blood glucose levels.

There are a number of sulphonylureas. In the UK, gliclazide is the most commonly used; in contrast, in the USA, glibenclamide (also known as glyburide) is widely used. Glibenclamide, however, is long-acting and prone to inducing hypoglycaemia, so should be avoided in older patients. Other sulphonylureas include glimepiride and glipizide. The dose–response of all sulphonylureas is steepest at low doses; little additional benefit is obtained when the dose is increased above half-maximal doses.

**Alpha-glucosidase inhibitors**

The $\alpha$-glucosidase inhibitors delay carbohydrate absorption in the gut by inhibiting disaccharidases. Acarbose and miglitol are available and are taken with each meal. Both lower post-prandial blood glucose and modestly improve overall glycaemic control. They can be combined with a sulphonylurea. The main side-effects are flatulence, abdominal bloating and diarrhoea. They are used widely in the Far East but infrequently in the UK.

**Thiazolidinediones**

**Mechanism of action**

These drugs (also called TZDs, ‘glitazones’ or PPAR$\gamma$ agonists) bind and activate peroxisome proliferator-activated receptor-$\gamma$, a nuclear receptor present mainly in adipose tissue, which regulates the expression of several genes involved in metabolism. TZDs enhance the actions of endogenous insulin, both directly (in the adipose cells) and indirectly (by altering release of ‘adipokines’, such as adiponectin, which alter insulin sensitivity in the liver). Plasma insulin concentrations are not increased and hypoglycaemia does not occur. TZDs increase pre-adipocyte differentiation, resulting in an increase in fat mass and body weight.

**Clinical use**

TZDs have been prescribed widely since the late 1990s but a number of adverse effects have become apparent and their use has declined. One popular TZD, rosiglitazone, was reported to increase the risk of myocardial infarction and was withdrawn in 2010. The other TZD in common use, pioglitazone, does not appear to increase the risk of myocardial infarction but may exacerbate cardiac failure by causing fluid retention, and recent data show that it increases the risk of bone fracture and possibly bladder cancer. These observations have led to a dramatic reduction in the use of pioglitazone.

Pioglitazone can be very effective at lowering blood glucose in some patients and appears more effective in insulin-resistant patients. In addition, it has a beneficial effect in reducing fatty liver and NASH (p. 882). Pioglitazone is usually added to metformin with or without sulphonylurea therapy (see Fig. 20.10). It may be given with insulin therapy, when it can be very effective, but the combination of insulin and TZDs markedly increases fluid retention and risk of cardiac failure, so should be used with caution.

**Incretin-based therapies: DPP-4 inhibitors and GLP-1 receptor agonists**

The incretin effect is the augmentation of insulin secretion seen when a glucose stimulus is given orally rather than intravenously, and reflects the release of incretin peptides from the gut (see Fig. 20.3). The incretin hormones are primarily glucagon-like peptide 1 (GLP-1) and gastric inhibitory polypeptide (GIP), which act to potentiate insulin secretion (see Fig. 20.2). These are rapidly broken down by dipeptidyl peptidase 4 (DPP-4). The incretin effect is diminished in type 2 diabetes, and this has stimulated the development of two incretin-based therapeutic approaches.

The ‘gliptins’, or DPP-4 inhibitors, prevent breakdown and therefore enhance concentrations of endogenous GLP-1 and GIP. The first DPP-4 inhibitor to market was sitagliptin; others now available include vildagliptin, saxagliptin, linagliptin and alogliptin. These drugs are very well tolerated and are weight-neutral (see Box 20.26). Recent cardiovascular outcome studies have shown mixed results with the DPP-4 inhibitors. The Trial to Evaluate Cardiovascular Outcomes after Treatment with Sitagliptin (TECOS) study reported no adverse cardiovascular outcomes for sitagliptin, but the Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus – Thrombolysis in Myocardial Infarction (SAVOR-TIMI) study found an increased risk of heart failure in patients treated with saxagliptin.

The GLP-1 receptor agonists have a similar structure to GLP-1 but have been modified to resist breakdown by DPP-4. These agents are not orally active and have to be given by subcutaneous injection. However, they have a key advantage over the DPP-4 inhibitors: because the GLP-1 activity achieved is supra-physiological, it delays gastric emptying and, at the level of the hypothalamus, decreases appetite. Thus, injectable GLP-1 receptor agonists lower blood glucose and result in weight loss – an appealing therapy, as the majority of patients with type 2 diabetes are obese. Currently available GLP-1 receptor agonists include exenatide (twice daily), exenatide modified-release (once weekly), lixisenatide (once daily), liraglutide (once daily) and albiglutide (once weekly). Recently, GLP-1 receptor agonists and long-acting insulin analogue have been combined, enabling co-administration of insulin and GLP-1 receptor agonists with one injection. The GLP-1 receptor agonists vary in their side-effect profile, depending on whether they are administered daily or weekly, but the main side-effect that often limits use is nausea. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) study has recently demonstrated that liraglutide, when added to usual therapy, results in improved cardiovascular outcomes over placebo in patients at high risk for cardiovascular disease; this contrasts with the Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) study, which showed that lixisenatide was neutral with respect to cardiovascular disease.
All the incretin-acting drugs have been reported to be associated with an increased risk of pancreatitis, although this risk is small: between 1 and 10 cases per 1000 patients treated.

Unlike sulphonylureas, both incretin-based therapies promote insulin secretion only when there is a glucose ‘trigger’ for it. Thus, when the blood glucose is normal, the insulin secretion is not augmented and so these agents do not cause hypoglycaemia when used as monotherapy or with other drugs that do not cause hypoglycaemia.

**SGLT2 inhibitors**

The sodium and glucose transporter 2 (SGLT2) inhibitor, dapagliflozin, was licensed for use in 2012. Subsequently, canagliflozin and empagliflozin have also been licensed. Glucose is filtered freely in the renal glomeruli and reabsorbed in the proximal tubules. SGLT2 is involved in reabsorption of glucose (Fig. 20.12). Inhibition results in approximately 25% of the filtered glucose not being reabsorbed, with consequent glycosuria. Although this helps to lower blood glucose and results in calorie loss and subsequent weight loss, the glycosuria does also lead to genital fungal infections. There has been increasing use of these agents over the last few years; however, the recent announcement of the Empagliflozin, Cardiovascular Outcomes, and Mortality in Type 2 Diabetes (EMPA-REG Outcomes) trial has the potential to change dramatically the way these drugs are now used. Empagliflozin therapy resulted in a 35% reduction in cardiovascular mortality and a similar reduction in admissions to hospital with heart failure. This result was much greater than anticipated and the mechanism behind it is still being investigated, but this landmark study was the first to show such striking benefits in mortality reduction from a glucose-lowering agent; as such, these drugs should now, at the very least, be used in all patients who fulfil the inclusion criteria of the trial – prior myocardial infarction, coronary artery disease, stroke, unstable angina or occlusive peripheral arterial disease. Euglycaemic diabetic ketoacidosis (i.e. DKA not associated with marked hyperglycaemia) has been recognised as a rare complication of this class of drugs.
Management of diabetes

• Discomfort of injecting bigger volumes and also to reduce variability in insulin delivery from the subcutaneous depot. Therefore, U 200, U 300 and U 500 formulations of insulin are available, which are, respectively, two, three and five times more concentrated than standard insulin. Expert advice should be sought before using concentrated insulin because errors in prescribing can cause severe hypoglycaemia.

Subcutaneous multiple dose insulin therapy

In most patients, insulin is injected subcutaneously several times a day into the anterior abdominal wall, upper arms, outer thighs and buttocks (Box 20.28). Accidental intramuscular injection often occurs in children and thin adults. The rate of absorption of insulin may be influenced by many factors other than the insulin formulation, including the site, depth and volume of injection, skin temperature (warming), local massage and exercise. Absorption is delayed from areas of lipohypertrophy at injection sites, which results from the local trophic action of insulin, so repeated injection at the same site should be avoided. Other routes of administration (intravenous and intraperitoneal) are reserved for specific circumstances.

Fig. 20.13 Amino acid structure of insulin and insulin analogues. The areas in the shaded colours show the modifications made to the normal structure of insulin. These are important in altering the pharmacokinetic properties of the analogues.

Discomfort of injecting bigger volumes and also to reduce variability in insulin delivery from the subcutaneous depot. Therefore, U 200, U 300 and U 500 formulations of insulin are available, which are, respectively, two, three and five times more concentrated than standard insulin. Expert advice should be sought before using concentrated insulin because errors in prescribing can cause severe hypoglycaemia.

In most patients, insulin is injected subcutaneously several times a day into the anterior abdominal wall, upper arms, outer thighs and buttocks (Box 20.28). Accidental intramuscular injection often occurs in children and thin adults. The rate of absorption of insulin may be influenced by many factors other than the insulin formulation, including the site, depth and volume of injection, skin temperature (warming), local massage and exercise. Absorption is delayed from areas of lipohypertrophy at injection sites (p. 721), which results from the local trophic action of insulin, so repeated injection at the same site should be avoided. Other routes of administration (intravenous and intraperitoneal) are reserved for specific circumstances.

Once absorbed into the blood, insulin has a half-life of just a few minutes. It is removed mainly by the liver and also the kidneys, so plasma insulin concentrations are elevated in patients with liver disease or renal failure. Rarely, the rate of clearance can be affected by binding to insulin antibodies.
Insulin can be administered using a disposable plastic syringe with a fine needle (which can be re-used several times), but this has largely been replaced by pen injectors containing insulin in cartridges sufficient for multiple dosing. These are also available as pre-loaded disposable pens.

For the most part, insulin analogues have replaced soluble and isophane insulins, especially for people with type 1 diabetes, because they allow greater flexibility and convenience and reduce risk of hypoglycaemia (see Box 20.26). Unlike soluble insulin, which should be injected 30–60 minutes before eating, rapid-acting insulin analogues can be administered immediately before, during or even after meals, although are better injected 15 minutes before eating. Long-acting insulin analogues are also better able than isophane insulin to maintain ‘basal’ insulin levels for up to 24 hours.

Despite these pharmacokinetic benefits, the impact of insulin analogues on overall glycaemic control is minor, but studies consistently show a significant reduction in frequency of hypoglycaemia, particularly overnight.

The complications of insulin therapy are listed in Box 20.29; the most important of these is hypoglycaemia (p. 738). A common problem is fasting hyperglycaemia (’the dawn phenomenon’), which arises through a combination of the normal circadian rhythm and release of hormones such as growth hormone and cortisol during the later part of the night, as well as diminishing levels of overnight isophane insulin. The dawn phenomenon is not a consequence of prior nocturnal hypoglycaemia.

### Insulin dosing regimens

The choice of regimen depends on the desired degree of glycaemic control, the severity of underlying insulin deficiency, the patient’s lifestyle, and his or her ability to adjust the insulin dose. The time–action profile of different insulin regimens, compared to the secretory pattern of insulin in the non-diabetic state, is shown in Figure 20.14. People with type 1 diabetes are best managed by multiple daily insulin injections or an insulin pump. In type 2 diabetes, insulin is usually initiated as a once-daily long-acting insulin, either alone or in combination with oral antidiabetic agents. However, in time, more frequent insulin injections are usually required.

Twice-daily administration of a short-acting and intermediate-acting insulin (usually soluble and isophane insulins), given in combination before breakfast and the evening meal, is the simplest regimen and is still commonly used in many countries. Initially, two-thirds of the total daily requirement of insulin is given in the morning in a ratio of short-acting to intermediate-acting of 1 : 2, and the remaining third is given in the evening. Pre-mixed formulations are available that contain different proportions of soluble and isophane insulins (e.g. 30 : 70 and 50 : 50). These are useful as they avoid the need for directly mixing insulins, but are inflexible as the individual components cannot be adjusted independently. They need to be resuspended by shaking the vial several times before administration. Fixed-mixture insulins also have altered pharmacodynamic profiles, such that the peak insulin action and time to peak effect are significantly reduced compared with separately injecting the same insulins. This increases the risk of hypoglycaemia.

Multiple injection regimens (intensive insulin therapy) are popular, with short-acting insulin being taken before each meal, and intermediate- or long-acting insulin being injected once or twice daily (basal-bolus regimen, Box 20.30). This type of regimen is more physiological and allows greater freedom with regard to meal timing, as well more variable day-to-day physical activity.
Subcutaneous continuous insulin therapy

Subcutaneous continuous insulin therapy, commonly known as the insulin pump, is a system of insulin delivery that uses a battery-operated medical device to deliver insulin continuously to the individual with type 1 diabetes. Device configurations vary between manufacturers but will include the pump with controls, processing module and batteries, a disposable insulin reservoir, and a disposable insulin set including cannula for subcutaneous insertion and a tubing system to deliver insulin from the reservoir to the cannula. Some recent versions are disposable or semi-disposable and eliminate tubing from the infusion set (patch pumps).

Insulin pumps allow the individual more flexibility with bolus insulin injections in both timing and shape (e.g. using an extended bolus when covering high-fat/protein meals such as steak, or when diabetes is complicated by gastroparesis), and also in changing basal insulin infusion rates. This is especially useful overnight when basal rates can be reduced to prevent low glucose, but increased pre-dawn to prevent high glucose. In addition, the temporary basal rates can be used to lessen the risk of hypoglycaemia with exercise. Determining an individual’s basal rate on the pump requires help from a specialist, but in essence is determined by fasting for periods of at least 4 hours while periodically evaluating the blood glucose levels and adjusting the pump infusion rate to maintain glucose in the normal range. Basal rates will change and can be influenced by factors such as increasing duration of disease, puberty, weight gain or loss, drugs that affect insulin sensitivity (e.g. glucocorticoids), and a change in fitness levels with exercise on overall glycaemic control. An example of an insulin pump is shown in Figure 20.15.

Closed loop insulin therapy

A further iteration in insulin pump therapy in recent years is the development of a ‘closed loop’ system, also known as the artificial pancreas (Fig. 20.16). These systems aim to integrate insulin pumps with continuous glucose monitoring systems (CGMS). In a closed loop system, the CGMS device communicates with the insulin pump via a computerised program. This means that real-time glucose data obtained through the CGMS can be used to calculate an insulin dosage to be dispensed through the insulin pump (Fig. 20.17). Features might include a ‘low-glucose suspend’ function, where detection of hypoglycaemia or a glucose level falling below a pre-set threshold (e.g. 4.0 mmol/L (72 mg/dL)) signals the pump to stop dispensing insulin until the wearer can treat the hypoglycaemia with food or glucose tabs. Current clinical trials in children and adults in the hospital or free-living setting aim to determine how effective this approach will be in optimising management of type 1 diabetes. Widespread use may, however, be limited by cost.

Alternative routes of insulin delivery have also been investigated. Clinical trials with intrapulmonary (inhalation), transdermal and oral insulins are ongoing but as yet none has proven commercially viable. Inhaled insulin has been approved for use in the USA as a mealtime insulin, but experience with this is very limited.
Transplantation

Whole-pancreas transplantation is carried out in a small number of patients with diabetes each year, but it presents problems relating to exocrine pancreatic secretions and long-term immunosuppression is necessary. There are currently four main types of whole-pancreas transplantation:

- pancreas transplant alone
- simultaneous pancreas–kidney (SPK) transplant, when pancreas and kidney are transplanted simultaneously from the same deceased donor
- pancreas-after-kidney (PAK) transplant, when a cadaveric, or deceased, donor pancreas transplant is performed after a previous, and different, living or deceased donor kidney transplant
- simultaneous deceased donor pancreas and live donor kidney (SPLK) transplant.

The principal complications occurring immediately after surgery include thrombosis, pancreatitis, infection, bleeding and rejection. Prognosis is improving: 1 year after transplantation more than 95% of all patients are still alive and 80–85% of all pancreases are still functional. After transplantation, patients will need life-long immunosuppression, which carries with it an increased risk of infection and cancer.

An alternative form of transplantation is allogenic islet transplantation, which involves the transplantation of islets from a donor pancreas into a person with type 1 diabetes. The isolated pancreatic islets are usually infused into the patient’s liver via the portal vein. This approach has now been successfully adopted in a number of centres around the world (Fig. 20.18). At present, islet transplantation is usually suitable only for patients with unstable glycaemic control characterised by recurrent severe hypoglycaemia that cannot be corrected by standard conventional and intensive insulin therapies. Progress is being made towards meeting the needs of supply, purification and storage of islets, but problems remain relating to transplant rejection, and destruction by the patient’s autoantibodies against β cells. Nevertheless, the development of methods of inducing tolerance to transplanted islets and the potential use of stem cells (p. 58) mean that this may still prove the most promising approach in the long term.

Adoption of newer immunosuppressive protocols has resulted in far better outcomes and now nearly 50% of transplanted patients will be insulin-independent at 3 years post transplantation.

Management of diabetes in special situations

Diabetes in pregnancy

The management of women with pre-existing diabetes who are pregnant or who have developed diabetes in pregnancy (gestational diabetes) is discussed in detail on page 1278 and summarised in Box 20.31. This is a highly specialised area and requires careful and attentive management, as elevated maternal
Diabetes in pregnancy

- **Control of established diabetes before and during pregnancy**: must be meticulous, to reduce the risk of complications such as pre-eclampsia, congenital malformations and stillbirth.
- **Gestational diabetes**: most commonly an inability to increase insulin secretion adequately to compensate for pregnancy-induced insulin resistance.
- **Screening for gestational diabetes**: all women at high risk should have an oral glucose tolerance test at 24–28 weeks. Measurement of HbA1c and/or blood glucose at booking visit is usually recommended.
- **Management of gestational diabetes**: reduce intake of refined carbohydrate, and add metformin, glibenclamide and/or insulin if necessary to optimise glycaemic control.
- **Self-monitoring of glucose**: targets are a pre-prandial level of <5.3 mmol/L (95 mg/dL) and a 1-hour or 2-hour post-prandial level of <7.8 mmol/L (140 mg/dL) and <6.4 mmol/L (114 mg/dL), respectively.

Diabetes in adolescence

- **Type of diabetes**: type 1 diabetes is predominant in children and adolescents, but type 2 diabetes is now presenting in unprecedented numbers of obese, inactive teenagers. Monogenic diabetes (MODY) should also be considered (see Box 20.10, p. 733).
- **Physiological changes**: hormonal, physical and lifestyle changes in puberty affect dietary intake, exercise patterns and sensitivity to insulin, necessitating alterations in insulin regimen.
- **Emotional changes**: adolescence is a phase of transition into independence (principally from parental care). Periods of rebellion against parental control, experimentation (e.g. with alcohol) and a more chaotic lifestyle are common, and often impact adversely on control of diabetes.
- **Glycaemic control**: a temporary deterioration in control is common, although not universal. It is sometimes more important to maintain contact and engagement with a young person than to insist on tight glycaemic control.
- **Diabetic ketoacidosis**: a few adolescents and young adults present with frequent episodes of DKA, often because of non-adherence to insulin therapy. This is more common in females. Motivating factors may include weight loss, rebellion, and manipulation of family or schooling circumstances.
- **Adolescent diabetes clinics**: these challenges are best tackled with support from a specialised multidisciplinary team, including paediatricians, physicians, nurses and psychologists. Support is required for the patient and parents.

Blood glucose in pregnancy is associated with significant maternal and fetal morbidity.

**Children, adolescents and young adults with diabetes**

Most type 1 diabetes is diagnosed in children below 18 years of age, with peak incidence rates between 5 and 7 years of age and at puberty. The management of diabetes in children and adolescents presents particular challenges, which should be addressed in specialised clinics with multidisciplinary input (Box 20.32). Some of the unique aspects of childhood type 1 diabetes management include changing insulin sensitivity related to sexual maturity and physical growth, unique vulnerability to hypoglycaemia (especially in children below 6 years of age) and possibly hyperglycaemia, as well as DKA. In addition, family dynamics, child care and schooling, developmental stages and
ability to self-care all have to be considered in the management plan, as well as, in older children and adolescents, issues of body image, eating disorders and recreational drug and alcohol use. It is also notable that there is very limited clinical research in children with diabetes and so most recommendations are based on expert opinion. The prevalence of type 2 diabetes in those below 20 years has been increasing and is estimated to increase fourfold in the next 40 years. Management of these children and young adults is difficult.

Coeliac disease and thyroid disease are much more common in children with type 1 diabetes than in the general population and so it is currently recommended that these conditions are screened for. Current recommendations for screening in type 1 diabetes are shown in Box 20.33.

### Hyperglycaemia in acute medical illness

Hyperglycaemia is often found in patients who are admitted to hospital as an emergency. In most people this occurs in the context of a known diagnosis of diabetes; in some individuals, however, it is a consequence of stress hyperglycaemia (p. 728), while in others it is due to undiagnosed diabetes. Hyperglycaemia on admission to hospital is associated with increased length of stay and increased mortality in a wide variety of acute medical emergencies, including acute coronary syndrome and acute stroke. Intuitively, intensive glycaemic control with intravenous insulin should improve outcomes during acute illness. However, recent studies have shown that strategies aiming for near-normal blood glucose levels in acutely ill patients are associated with either increased mortality or no overall benefit. The reasons for the adverse outcomes are not established, but intensive glycaemic control is inevitably associated with an increased risk of hypoglycaemia because of the inherent limitations of modern insulins, the restricted frequency of glucose monitoring in a ward environment and the relative imprecision of near-patient blood glucose meters. The activation of the sympathetic nervous system and release of counter-regulatory hormones during acute hyperglycaemia could have deleterious consequences for the acutely ill patient.

There is no consensus on the optimum glucose targets in acutely ill patients but extremes of blood glucose should be avoided, and so a target of between 6 and 12 mmol/L (105 and 180 mg/dL) seems appropriate. Achieving such a target may require the use of intravenous insulin and dextrose in some individuals.

### Surgery and diabetes

Patients with diabetes are reported to have up to 50% higher perioperative mortality than patients without diabetes. Surgery causes catabolic stress and secretion of counter-regulatory hormones (including catecholamines and cortisol) in both normal and diabetic individuals. This results in increased glycogenolysis, gluconeogenesis, lipolysis, proteolysis and insulin resistance. Starvation exacerbates this process by increasing lipolysis. In the non-diabetic person, these metabolic effects lead to a secondary increase in the secretion of insulin, which exerts a controlling influence. In diabetic patients, either there is absolute deficiency of insulin (type 1 diabetes) or insulin secretion is delayed and impaired (type 2 diabetes), so that in untreated or poorly controlled diabetes, the uptake of metabolic substrate into tissues is significantly reduced, catabolism is increased and, ultimately, metabolic compensation in the form of DKA may develop in both types of diabetes. In addition, hyperglycaemia impairs wound healing and innate immunity, leading to increased risk of infection. Patients with diabetes are also more likely to have underlying pre-operative morbidity, especially cardiovascular disease. Finally, management errors in diabetes may cause dangerous hyperglycaemia or hypoglycaemia. Careful pre-operative assessment and perioperative management are therefore essential, ideally with support from the diabetes specialist team.

#### Pre-operative assessment

Unless a surgical intervention is an emergency, patients with diabetes should be assessed well in advance of surgery so that poor glycaemic control and other risk factors can be addressed (Box 20.34). There is good evidence that a higher HbA1c is associated with adverse perioperative outcome. In general, an upper limit for an acceptable HbA1c should be between 64 and 75 mmol/mol (8% and 9%). However, since optimisation of care may take weeks or months to achieve, the benefits need to be weighed against the need for early surgical intervention.

#### Perioperative management

Figure 20.19 outlines a general approach to perioperative management of diabetes, although this may need to be adapted according to the patient, the surgical procedure and local guidelines. Patients with diabetes who are considered low-risk can attend as day cases or be admitted on the day of surgery.
Complications of diabetes

Despite all the treatments now available, the outcome for patients with diabetes remains disappointing. Long-term complications of diabetes still cause significant morbidity and mortality (Boxes 20.35 and 20.36).

Excess mortality in diabetes is caused mainly by large blood vessel disease, particularly myocardial infarction and stroke. Macrovascular disease also causes substantial morbidity from myocardial infarction, stroke, angina, cardiac failure and intermittent claudication. The pathological changes of atherosclerosis in diabetic patients are similar to those in the non-diabetic population but occur earlier in life and are more extensive and severe. Diabetes amplifies the effects of the other major cardiovascular risk factors: smoking, hypertension and dyslipidaemia (Fig. 20.20). Moreover, patients with type 2 diabetes are more likely to have additional cardiovascular risk factors, which co-segregate with insulin resistance in the metabolic syndrome (p. 730). Mortality statistics from the USA indicate that cardiovascular death rates are 1.7 times higher in adults with diabetes aged 20 years or older compared to adults in the same age group who do not have diabetes, while similar figures for myocardial infarction show a 1.8 times greater rate. Hospitalisation rates for stroke were 1.5 times higher in adults with diabetes than in those without diabetes. In addition, 60% of non-traumatic amputations among people aged 20 years or older were reported to be in people with diabetes. Type 1 diabetes is also associated with increased cardiovascular risk. Recent data from Scotland show that the age-adjusted incidence rate ratio for first cardiovascular event was 3 times higher in women and 2.3 times higher in men with type 1 diabetes compared to those without diabetes.

Occasionally, patients may be admitted the night before to ensure optimal management.

Post-operative management

Patients who need to continue fasting after surgery should be maintained on intravenous insulin and fluids until they are able to eat and drink (Fig. 20.19). During this time, care must be taken with fluid balance and electrolyte levels. Insulin infusion necessitates dextrose infusion to maintain a supply of glucose but this combination drives down plasma potassium (p. 360) and can result in hyponatraemia. Intravenous fluids during prolonged insulin infusion should therefore include saline and potassium supplementation. UK guidelines recommend the use of dextrose/saline (0.45% saline with 5% dextrose and 0.15% potassium chloride).

Once a patient’s usual treatment has been reinstated, care must be taken to continue to control the blood glucose, ideally between 6 and 10 mmol/L (105–180 mg/dL), in order to optimise wound healing and recovery. Patients normally controlled on tablets may require temporary subcutaneous insulin treatment until the increased ‘stress’ of surgery, wound healing or infection has resolved.

Fig. 20.19 Management of diabetic patients undergoing surgery and general anaesthesia. (eGFR = estimated glomerular filtration rate; GLP-1 = glucagon-like peptide 1; IV = intravenous; U&Es = urea and electrolytes)
Disease of small blood vessels is a specific complication of diabetes and is termed diabetic microangiopathy. It contributes to mortality through renal failure caused by diabetic nephropathy, and is responsible for substantial morbidity and disability: for example, blindness from diabetic retinopathy, difficulty in walking, chronic ulceration of the feet from peripheral neuropathy, and bowel and bladder dysfunction from autonomic neuropathy. The risk of microvascular disease is positively correlated with the duration and degree of sustained hyperglycaemia, however it is caused and at whatever age it develops.

Pathophysiology

The histopathological hallmark of diabetic microangiopathy is thickening of the capillary basement membrane, with associated increased vascular permeability, which occurs throughout the body. The development of the characteristic clinical syndromes of diabetic retinopathy, nephropathy, neuropathy and accelerated atherosclerosis is thought to result from the local response to generalised vascular injury. For example, in the wall of large vessels, increased permeability of arterial endothelium, particularly when combined with hyperinsulinaemia and hypertension, may increase the deposition of atherogenic lipoproteins. The mechanisms linking hyperglycaemia to these pathological changes are, however, poorly characterised.

Preventing diabetes complications

Glycaemic control

The evidence that improved glycaemic control decreases the risk of developing microvascular complications of diabetes was established by the DCCT in type 1 diabetes and the UKPDS in type 2 diabetes. The DCCT was a large study that lasted 9 years; it randomised patients with type 1 diabetes to intensive treatment (mean HbA1c 53 mmol/mol) and conventional treatment (mean HbA1c 75 mmol/mol). There was a 60% overall reduction in the risk of developing diabetic complications in patients with type 1 diabetes on intensive therapy with strict glycaemic control, compared with those on conventional therapy. No single factor other than glycaemic control had a significant effect on outcome. However, the group that was intensively treated to lower blood glucose had three times the rate of severe hypoglycaemia. The UKPDS randomised patients to intensive treatment (mean HbA1c 53 mmol/mol) versus conventional treatment (mean HbA1c 64 mmol/mol). This study showed that, in type 2 diabetes, the frequency of diabetic complications is lower and progression is slower with good glycaemic control and effective treatment of hypertension, irrespective of the type of therapy used. Extrapolation from the UKPDS suggests that, for every 11 mmol/mol
and accounts for between 20% and 50% of patients starting renal replacement therapy.

About 30% of patients with type 1 diabetes have developed diabetic nephropathy 20 years after diagnosis, but the risk after this time falls to less than 1% per year, and from the outset the risk is not equal in all patients (Box 20.38). The risk of nephropathy in Caucasian populations with type 2 diabetes is similar to those with type 1 diabetes but the rate of progression may be exacerbated by concomitant obesity and other risk factors. The risk of nephropathy is much greater in some ethnic groups, with epigenetic and genetic factors thought to influence this increased risk. Some patients do not develop nephropathy, however, despite having long-standing, poorly controlled diabetes, suggesting that they do not have a genetic predisposition. While variants in a few genes have been implicated in diabetic nephropathy, the major differences in individual risk remain unexplained. With improved standards of care focusing on glycaemic control and blood pressure lowering, the proportion of patients with overt nephropathy is reducing; however, due to the global rise in the incidence of type 2 diabetes, the prevalent number of people with diabetes and end-stage renal failure continues to rise.

The pathophysiology is not fully understood and there are several postulated mechanisms by which hyperglycaemia causes the pathological changes seen in diabetic nephropathy. The central features are activation of the renin–angiotensin system, leading to both intrarenal and systemic effects, as well as direct toxic effects of prolonged hyperglycaemia, leading to renal inflammation and fibrosis. The pattern of progression of renal abnormalities in diabetes is shown schematically in Figure 20.21. Pathologically, the first changes coincide with the onset of microalbuminuria and include thickening of the glomerular basement membrane and accumulation of matrix material in the mesangium. Subsequently, nodular deposits (Fig. 20.22) are characteristic, and glomerulosclerosis worsens as heavy proteinuria develops, until glomeruli are progressively lost and renal function deteriorates.

**Diabetes management in old age**

- **Glycaemic control**: the optimal target for glycaemic control in older people has yet to be determined. Strict glycaemic control should be avoided in frail patients with comorbidities and in older patients with long duration of diabetes.

- **Cognitive function and affect**: may benefit from improved glycaemic control but it is important to avoid hypoglycaemia.

- **Hypoglycaemia**: older people have reduced symptomatic awareness of hypoglycaemia and limited knowledge of symptoms, and are at greater risk of, and from, hypoglycaemia.

- **Mortality**: the mortality rate of older people with diabetes is more than double that of age-matched non-diabetic people, largely because of increased deaths from cardiovascular disease.

**Diabetic retinopathy**

Diabetic retinopathy (DR) is one of the most common causes of blindness in adults between 30 and 65 years of age in developed countries. The prevalence of DR increases with duration of diabetes, and almost all individuals with type 1 diabetes and the majority of those with type 2 diabetes will have some degree of DR after 20 years. The pathogenesis, clinical features and management of diabetic retinopathy, as well as screening and prevention, are described on page 1174. Other causes of visual loss in type 2 diabetes are also covered in Chapter 27.

**Diabetic nephropathy**

Diabetic nephropathy is an important cause of morbidity and mortality in both type 1 and type 2 diabetes. It is now the most common cause of end-stage renal failure in developed countries.
risk of progression of nephropathy and of cardiovascular disease by:

- aggressive reduction of blood pressure
- aggressive reduction of cardiovascular risk factors
- optimisation of glycaemic control

Blockade of the renin–angiotensin system using either ACE inhibitors or angiotensin 2 receptor blockers (ARBs) has been shown to have an additional benefit over similar levels of blood pressure control achieved with other antihypertensive agents and is recommended as first-line therapy. The addition of a diuretic and/or salt restriction increase both the anti-proteinuric and antihypertensive effect of angiotensin blockade and therefore constitute an ideal second-line treatment. The benefit from blockade of the renin–angiotensin system arises from a reduction in the angiotensin II–mediated vasoconstriction of efferent arterioles in the glomeruli (see Fig. 15.1D, p. 385). The resulting dilatation of these vessels decreases glomerular filtration pressure and, therefore, the hyperfiltration and protein leak. Both ACE inhibitors and ARBs increase risk of hyperkalaemia (p. 362) and, in the presence of renal artery stenosis (p. 406), may induce marked deterioration in renal function. Therefore, electrolytes and renal function should be checked after initiation or each dose increase. If blockade of the renin–angiotensin system is not possible, blood pressure should be managed with standard treatment, such as calcium channel blockers and diuretics. There may be a role for spironolactone (an aldosterone antagonist) but this is limited by hyperkalaemia.

Halving the amount of albuminuria with an ACE inhibitor or ARB results in a nearly 50% reduction in long-term risk of progression to end-stage renal disease. Some patients do progress, however, with worsening renal function. Renal replacement therapy (p. 420) is often required at a higher eGFR than in other causes of renal failure, due to fluid overload or symptomatic uraemia.

Renal transplantation dramatically improves the life of many, and any recurrence of diabetic nephropathy in the allograft is usually too slow to be a serious problem; associated macrovascular and microvascular disease elsewhere may still progress, however. Pancreatic transplantation (generally carried out at the same time as renal transplantation) can produce insulin independence and delay or reverse microvascular disease, but the supply of organs is limited and this option is available to few. For further information on management, see Chapter 15.

**Diabetic neuropathy**

Diabetic neuropathy causes substantial morbidity and increases mortality. It is diagnosed on the basis of symptoms and signs, after the exclusion of other causes of neuropathy (p. 1138). Depending on the criteria used for diagnosis, it affects between 50% and 90% of patients with diabetes, and of these, 15–30% will have painful diabetic neuropathy (PDN). Like retinopathy, neuropathy occurs secondary to metabolic disturbance, and prevalence is related to the duration of diabetes and the degree of metabolic control.

Pathological features can occur in any peripheral nerves. They include axonal degeneration of both myelinated and unmyelinated fibres, with thickening of the Schwann cell basal lamina, patchy segmental demyelination and abnormal intraneural capillaries (with basement membrane thickening and microthrombi).

Various classifications of diabetic neuropathy have been proposed. One is shown in Box 20.40 but motor, sensory and autonomic nerves may be involved in varying combinations, so that clinically mixed syndromes usually occur.

**Clinical features**

**Symmetrical sensory polyneuropathy**

This is frequently asymptomatic. The most common clinical signs are diminished perception of vibration sensation distally, ‘glove
Complications of diabetes

• Pressure on the plantar aspects of the metatarsal heads, with the development of callus skin at these and other pressure points. Electrophysiological tests (p. 1074) demonstrate slowing of both motor and sensory conduction, and tests of vibration sensitivity and thermal thresholds are abnormal.

A diffuse small-fibre neuropathy causes altered perception of pain and temperature, and is associated with symptomatic autonomic neuropathy; characteristic features include foot ulcers and Charcot neuroarthropathy.

Asymmetrical motor diabetic neuropathy

Sometimes called diabetic amyotrophy, this presents as severe and progressive weakness and wasting of the proximal muscles of the lower (and occasionally the upper) limbs. It is commonly accompanied by severe pain, felt mainly on the anterior aspect of the leg, and hyperaesthesia and paraesthesiae. Sometimes there may also be marked loss of weight (‘neuropathic cachexia’). The patient may look extremely ill and be unable to get out of bed. Tendon reflexes may be absent on the affected side(s). Sometimes there are extensor planter responses and the cerebrospinal fluid protein is often raised. This condition is thought to involve acute infarction of the lower motor neurons of the lumbar sacral plexus. Other lesions involving this plexus, such as neoplasms and lumbar disc disease, must be excluded. Although recovery usually occurs within 12 months, some deficits are permanent. Management is mainly supportive.
Mononeuropathy
Either motor or sensory function can be affected within a single peripheral or cranial nerve. Unlike the gradual progression of distal symmetrical and autonomic neuropathies, mononeuropathies are severe and of rapid onset, but they eventually recover. The nerves most commonly affected are the 3rd and 6th cranial nerves (resulting in diplopia), and the femoral and sciatic nerves. Rarely, involvement of other single nerves results in paresis and paraesthesiae in the thorax and trunk (truncal radiculopathies).

Nerve compression palsies are more common in diabetes, frequently affecting the median nerve and giving the clinical picture of carpal tunnel syndrome, and less commonly the ulnar nerve. Lateral popliteal nerve compression occasionally causes foot drop. Compression palsies may be more common because of glycosylation and thickening of connective tissue and/or because of increased susceptibility of nerves affected by diabetic microangiopathy.

Autonomic neuropathy
This is not necessarily associated with peripheral somatic neuropathy. Parasympathetic or sympathetic nerves may be predominantly affected in one or more visceral systems. The resulting symptoms and signs are listed in Box 20.41 and tests of autonomic function in Box 20.42. The development of autonomic neuropathy is related to poor metabolic control less clearly than to somatic neuropathy, and improved control rarely results in improved symptoms. Within 10 years of developing overt symptoms of autonomic neuropathy, 30–50% of patients are dead, many from sudden cardiorespiratory arrest. Patients with postural hypotension (a drop in systolic pressure of 30 mmHg or more on standing from the supine position) have the highest subsequent mortality.

Gastroparesis
Gastroparesis is diagnosed when there is an objectively measured delay in gastric emptying in the absence of mechanical obstruction. It is most commonly a manifestation of autonomic neuropathy in diabetes, but can occur with eating disorders such as anorexia nervosa or bulimia that are also associated with diabetes. Prevalence rates are estimated to be approximately 5% in type 1 diabetes and 1% in type 2 diabetes. The main symptoms are chronic nausea, vomiting (especially of undigested food), abdominal pain and a feeling of fullness/early satiety. Diagnosis is most commonly made by 99m-technetium scintigraphy following a solid-phase meal with standard imaging over 4 hours. In this test it is important to recognise that high glucose levels can delay gastric emptying and so every attempt should be made to conduct the test when glucose levels are below 15 mmol/L (270 mg/dL). Other tests include upper gastrointestinal endoscopy, wireless motility capsules and breath testing (pp. 774, 776 and 777). Management is difficult, with glucose levels directly impacting on gastric motility and, conversely, gastroparesis affecting absorption of ingested carbohydrate. Insulin pump therapy may be especially useful in this context; patients on conventional injection therapy may benefit from injecting rapid-acting insulin after a meal rather than before. Recommended dietary changes include following low-fibre and low-residue diets, as well as eating smaller amounts more frequently. Enteral nutrition is rarely required unless gastroparesis is very severe. Recommended pharmacological and interventional therapy is shown in Box 20.43.

Erectile dysfunction
Erectile failure (impotence) affects 30% of diabetic males and is often multifactorial. Although neuropathy and vascular causes are common, psychological factors, including depression, anxiety and reduced libido, may be partly responsible. Alcohol and antihypertensive drugs, such as thiazide diuretics and β-adrenoceptor antagonists (β-blockers), may cause sexual dysfunction and in some patients there may be an endocrine

of diabetes accounts for more inpatient days than any other admission in diabetic patients. Treatment of the foot complications of diabetes accounts for more inpatient days than any other diabetes-related complication.

Aetiology
Foot ulceration occurs as a result of trauma (often trivial) in the presence of neuropathy and/or peripheral vascular disease.
of weight-bearing on the affected foot. The rationale is that if no pressure is applied through the foot, the destructive process involving the bones will not result in significant deformity when the acute inflammatory process subsides. Immobilisation is often achieved by a total contact plaster cast or ‘aircast’ boot. The acute phase frequently lasts 3–6 months and sometimes longer. In the post-acute phase, there is consolidation and remodelling of fracture fragments, eventually resulting in a stable foot.

Fig. 20.24 Risk assessment and management of foot problems in diabetes. Adapted from Scottish Intercollegiate Guidelines Network (SIGN) guideline number 116.

### 20.45 Care of the feet in patients with diabetes

#### Preventive advice
- **All diabetic patients**
  - Inspect feet every day
  - Wash feet every day
  - Moisturise skin if dry
  - Cut or file toenails regularly
  - Change socks or stockings every day
  - Avoid walking barefoot
- **Moderate- and high-risk patients**
  - Do not attempt corn removal
  - Avoid high and low temperatures

#### Podiatric care
- A podiatrist is an integral part of the diabetes team to ensure regular and effective podiatry and to educate patients in care of the feet

#### Orthotic footwear
- Specially manufactured and fitted orthotic footwear is required to prevent recurrence of ulceration and to protect the feet of patients with Charcot neuroarthropathy

Diseases of the gastrointestinal tract are a major cause of morbidity and mortality. Approximately 10% of all GP consultations in the UK are for indigestion and 1 in 14 is for diarrhoea. Infective diarrhoea and malabsorption are responsible for much ill health and many deaths in the developing world. The gastrointestinal tract is the most common site for cancer development. Colorectal cancer is the third most common cancer in men and women and population-based screening programmes exist in many countries. Functional bowel disorders affect up to 10–15% of the population and consume considerable health-care resources. The inflammatory bowel diseases, Crohn’s disease and ulcerative colitis, together affect 1 in 250 people in the Western world, with substantial associated morbidity.

Functional anatomy and physiology

Oesophagus, stomach and duodenum

The oesophagus is a muscular tube that extends 25 cm from the cricoid cartilage to the cardiac orifice of the stomach. It has an upper and a lower sphincter. A peristaltic swallowing wave propels the food bolus into the stomach (Fig. 21.1).

The stomach acts as a ‘hopper’, retaining and grinding food, and then actively propelling it into the upper small bowel (Fig. 21.2).
Gastric secretion

Gastrin, histamine and acetylcholine are the key stimulants of acid secretion. Hydrogen and chloride ions are secreted from the apical membrane of gastric parietal cells into the lumen of the stomach by a hydrogen–potassium adenosine triphosphatase (ATPase) (‘proton pump’) (Fig. 21.3). The hydrochloric acid sterilises the upper gastrointestinal tract and converts pepsinogen, which is secreted by chief cells, to pepsin. The glycoprotein intrinsic factor, secreted in parallel with acid, is necessary for vitamin B₁₂ absorption.

Gastrin, somatostatin and ghrelin

The hormone gastrin is produced by G cells in the antrum, whereas somatostatin is secreted from D cells throughout the stomach. Gastrin stimulates acid secretion and mucosal growth while somatostatin suppresses it. Ghrelin, secreted from oxyntic glands, stimulates acid secretion but also appetite and gastric emptying.

Protective factors

Bicarbonate ions, stimulated by prostaglandins, mucins and trefoil factor family (TFF) peptides, together protect the gastro-

---

**Fig. 21.3 Control of acid secretion.** Gastrin released from antral G cells in response to food (protein) binds to cholecystokinin receptors (CCK-2R) on the surface of enterochromaffin-like (ECL) cells, which in turn release histamine. The histamine binds to H₂ receptors on parietal cells and this leads to secretion of hydrogen ions in exchange for potassium ions at the apical membrane. Parietal cells also express CCK-2R and it is thought that activation of these receptors by gastrin is involved in regulatory proliferation of parietal cells. Cholinergic (vagal) activity and gastric distension also stimulate acid secretion; somatostatin, vasoactive intestinal polypeptide (VIP) and gastric inhibitory polypeptide (GIP) may inhibit it. (ACH-R = acetylcholine receptor; ATPase = adenosine triphosphatase)

**Small intestine**

The small bowel extends from the ligament of Treitz to the ileocaecal valve (Fig. 21.4). During fasting, a wave of peristaltic activity passes down the small bowel every 1–2 hours. Entry of food into the gastrointestinal tract stimulates small bowel peristaltic activity. Functions of the small intestine are:

- digestion (mechanical, enzymatic and peristaltic)
- absorption – the products of digestion, water, electrolytes and vitamins
- protection against ingested toxins
- immune regulation.

---

**Fig. 21.4 Small intestine: anatomy.** Epithelial cells are formed in crypts and differentiate as they migrate to the tip of the villi to form enterocytes (absorptive cells) and goblet cells.
Digestion and absorption

**Fat**
Dietary lipids comprise long-chain triglycerides, cholesterol esters and lecithin. Lipids are insoluble in water and undergo lipolysis and incorporation into mixed micelles before they can be absorbed into enterocytes along with the fat-soluble vitamins A, D, E and K. The lipids are processed within enterocytes and pass via lymphatics into the systemic circulation. Fat absorption and digestion can be considered as a stepwise process, as outlined in Figure 21.5.

**Carbohydrates**
Starch is hydrolysed by salivary and pancreatic amylases to:
- α-limit dextrins containing 4–8 glucose molecules
- the disaccharide maltose
- the trisaccharide maltotriose.

Disaccharides are digested by enzymes fixed to the microvillous membrane to form the monosaccharides glucose, galactose and fructose. Glucose and galactose enter the cell by an energy-requiring process involving a carrier protein, and fructose enters by simple diffusion.

**Protein**
The steps involved in protein digestion are shown in Figure 21.6. Intragastric digestion by pepsin is quantitatively modest but important because the resulting polypeptides and amino acids stimulate cholecystokinin (CCK) release from the mucosa of the proximal jejunum, which in turn stimulates release of pancreatic proteases, including trypsinogen, chymotrypsinogen, pro-elastases and procarboxypeptidases, from the pancreas. On exposure to brush border enterokinase, inert trypsinogen is converted to the active proteolytic enzyme trypsin, which activates the other pancreatic pro-enzymes. Trypsin digests proteins to produce oligopeptides, peptides and amino acids. Oligopeptides are further hydrolysed by brush border enzymes to yield dipeptides, tripeptides and amino acids. These small peptides and the amino acids are actively transported into the enterocytes, where intracellular peptidases further digest peptides to amino acids. Amino acids are then actively transported across the basal cell membrane of the enterocyte into the portal circulation and the liver.

---

**Fig. 21.5 Fat digestion.** Step 1: Luminal phase. Fatty acids stimulate cholecystokinin (CCK) release from the duodenum and upper jejunum. The CCK stimulates release of amylase, lipase, colipase and proteases from the pancreas, causes gallbladder contraction and relaxes the sphincter of Oddi, allowing bile to flow into the intestine. Step 2: Fat solubilisation. Bile acids and salts combine with dietary fat to form mixed micelles, which also contain cholesterol and fat-soluble vitamins. Step 3: Digestion. Pancreatic lipase, in the presence of its co-factor, colipase, cleaves long-chain triglycerides, yielding fatty acids and monoglycerides. Step 4: Absorption. Mixed micelles diffuse to the brush border of the enterocytes. Within the brush border, long-chain fatty acids bind to proteins, which transport the fatty acids into the cell, whereas cholesterol, short-chain fatty acids, phospholipids and fat-soluble vitamins enter the cell directly. The bile salts remain in the small intestinal lumen and are actively transported from the terminal ileum into the portal circulation and returned to the liver (the enterohepatic circulation). Step 5: Re-esterification. Within the enterocyte, fatty acids are re-esterified to form triglycerides. Triglycerides combine with cholesterol ester, fat-soluble vitamins, phospholipids and apoproteins to form chylomicrons. Step 6: Transport. Chylomicrons leave the enterocytes by exocytosis, enter mesenteric lymphatics, pass into the thoracic duct and eventually reach the systemic circulation.
**Fig. 21.6 Protein digestion.** (CCK = cholecystokinin)

**Water and electrolytes**
Absorption and secretion of electrolytes and water occur throughout the intestine. Electrolytes and water are transported by two pathways:
- the paracellular route, in which passive flow through tight junctions between cells is a consequence of osmotic, electrical or hydrostatic gradients
- the transcellular route across apical and basolateral membranes by energy-requiring specific active transport carriers (pumps).

In healthy individuals, fluid balance is tightly controlled, such that only 100 mL of the 8 litres of fluid entering the gastrointestinal tract daily is excreted in stools (Fig. 21.7).

**Vitamins and trace elements**
Water-soluble vitamins are absorbed throughout the intestine. The absorption of folic acid, vitamin B₁₂, calcium and iron is described on page 943.

**Protective function of the small intestine**

**Physical defence mechanisms**
There are several levels of defence in the small bowel (Fig. 21.8). Firstly, the gut lumen contains host bacteria (see below), mucins and secreted antibacterial products, including defensins and immunoglobulins that help combat pathogenic infections. Secondly, epithelial cells have relatively impermeable brush border membranes and passage between cells is prevented by tight and adherens junctions. These cells can react to foreign peptides (‘innate immunity’) using pattern recognition receptors found on cell surfaces (Toll receptors) or intracellularly. Lastly, in the subepithelial layer, immune responses occur under control of the adaptive immune system in response to pathogenic compounds.

**Immunological defence mechanisms**
Gastrointestinal mucosa-associated lymphoid tissue (MALT) constitutes 25% of the total lymphatic tissue of the body and is at the heart of adaptive immunity. Within Peyer’s patches,
hormones (Fig. 21.9) and are activated by trypsin. Bicarbonate-rich fluid is secreted from ductular cells to produce an optimum alkaline pH for enzyme activity. The endocrine pancreas is discussed in Chapters 18 and 20.

**Colon**

The colon (Fig. 21.10) absorbs water and electrolytes. It also acts as a storage organ and has contractile activity. Two types of contraction occur. The first of these is segmentation (ring contraction), which leads to mixing but not propulsion; this promotes absorption of water and electrolytes. Propulsive (peristaltic contraction) waves occur several times a day and propel faeces to the rectum. All activity is stimulated after meals through the gastrocolic reflex in response to release of hormones such as 5-hydroxytryptamine (5-HT, serotonin), motilin and CCK. Faecal continence depends on maintenance of the anorectal angle and tonic contraction of the external anal sphincters. On defecation, there is relaxation of the anorectal muscles, increased intra-abdominal pressure from the Valsalva manoeuvre and contraction of abdominal muscles, and relaxation of the anal sphincters.

**B lymphocytes** differentiate to plasma cells following exposure to antigens and these migrate to mesenteric lymph nodes to enter the blood stream via the thoracic duct. The plasma cells return to the lamina propria of the gut through the circulation and release immunoglobulin A (IgA), which is transported into the lumen of the intestine. Intestinal T lymphocytes help localise plasma cells to the site of antigen exposure, as well as producing inflammatory mediators. Macrophages in the gut phagocytose foreign materials and secrete a range of cytokines, which mediate inflammation. Similarly, activation of mast-cell surface IgE receptors leads to degranulation and release of other molecules involved in inflammation.

**Pancreas**

The exocrine pancreas (Box 21.1) is necessary for the digestion of fat, protein and carbohydrate. Pro-enzymes are secreted from pancreatic acinar cells in response to circulating gastrointestinal hormones (Fig. 21.9) and are activated by trypsin. Bicarbonate-rich fluid is secreted from ductular cells to produce an optimum alkaline pH for enzyme activity. The endocrine pancreas is discussed in Chapters 18 and 20.
Intestinal microbiota

The human microbiota comprises $10^{14}$ microbial residents in the human body, vastly outnumbering host cells. Indeed, the number of bacterial genes in the microbiota genome exceeds that of the host by 100-fold or more. This represents a vast ecosystem that is central to health and homeostasis, and is disordered in disease. In terms of nomenclature, ‘microbiota’ refers to the microorganisms that live in a particular niche, while ‘microbiome’ refers to the collective genomes of these microbiota. The metabolic capacity of the gut microbiota is equivalent to that of the liver. The Human Microbiome Project revealed that there are unique communities at different body sites and in the gut particular phyla predominate; namely, Firmicutes, Bacteriodetes, Proteobacteria and Actinobacteria. There is a degree of heritability of this microbiota, as shown in twin studies, but it is clear that there are many environmental factors that can impact, including diet, drugs, physical activity, smoking, stress and natural ageing. Generally, we acquire our adult intestinal microbiota by the age of 2 years. A dysbiosis or imbalance between the different components of the intestinal microbiota has been associated with diseases of the gastrointestinal tract, such as inflammatory bowel disease and colorectal cancer; liver disease, including hepatocellular carcinoma; and pathologies outside the gastrointestinal tract, such as diabetes, obesity, cardiovascular disorders, cerebrovascular disorders, asthma and psychiatric disorders, such as depression. Many challenges remain in understanding the intestinal microbiota and how it impacts on health and disease. It is not clear what constitutes a ‘healthy’ phenotype; there are questions over best sampling practice from either the faecal stream or the mucosa; and there are technical considerations to ensure consistency in methodologies and data analysis.

Control of gastrointestinal function

Secretion, absorption, motor activity, growth and differentiation of the gut are all modulated by a combination of neuronal and hormonal factors.

The nervous system and gastrointestinal function

The central nervous system (CNS), the autonomic system (ANS) and the enteric nervous system (ENS) interact to regulate gut function. The ANS comprises:

- parasympathetic pathways (vagal and sacral efferent), which are cholinergic, and increase smooth muscle tone and promote sphincter relaxation
- sympathetic pathways, which release noradrenaline (norepinephrine), reduce smooth muscle tone and stimulate sphincter contraction.

The enteric nervous system

In conjunction with the ANS, the ENS senses gut contents and conditions, and regulates motility, fluid exchange, secretion, blood flow and other key gut functions. It comprises two major networks intrinsic to the gut wall. The myenteric (Auerbach’s) plexus in the smooth muscle layer regulates motor control; and the submucosal (Meissner’s) plexus exerts secretory control over the epithelium, entero-endocrine cells and submucosal vessels. Together, theseplexuses form a two-layered neuronal mesh along the length of...
the gut. Although connected centrally via the ANS, the ENS can function autonomously using a variety of transmitters, including acetylcholine, noradrenaline (norepinephrine), 5-HT, nitric oxide, substance P and calcitonin gene-related peptide (CGRP). There are local reflex loops within the ENS but also loops involving the coeliac and mesenteric ganglia and the paravertebral ganglia. The parasympathetic system generally stimulates motility and secretion, while the sympathetic system generally acts in an inhibitory manner.

**Peristalsis**

Peristalsis is a reflex triggered by gut wall distension, which consists of a wave of circular muscle contraction to propel contents from the oesophagus to the rectum. It can be influenced by innervation but functions independently. It results from a basic electrical rhythm originating from the interstitial cells of Cajal in the circular layer of intestinal smooth muscle. These are stellate cells of mesenchymal origin with smooth muscle features, which act as the ‘pacemaker’ of the gut.

**Migrating motor complexes**

Migrating motor complexes (MMCs) are waves of contraction spreading from the stomach to the ileum, occurring at a frequency of about 5 per minute every 90 minutes or so, between meals and during fasting. They may serve to sweep intestinal contents distally in preparation for the next meal and are inhibited by eating.

**Gut hormones**

The origin, action and control of the major gut hormones, peptides and non-peptide signalling transmitters are summarised in Box 21.2.

**Investigation of gastrointestinal disease**

A wide range of tests is available for the investigation of patients with gastrointestinal symptoms. These can be classified broadly into tests of structure, tests for infection and tests of function.

**Imaging**

**Plain X-rays**

Plain X-rays of the abdomen are useful in the diagnosis of intestinal obstruction or paralytic ileus, where dilated loops of bowel and (in the erect position) fluid levels may be seen (Fig. 21.11). Calcified lymph nodes, gallstones and renal stones can also be detected. Chest X-ray (performed with the patient in erect position) is useful in the diagnosis of suspected perforation, as it shows subdiaphragmatic free air (Fig. 21.11).
The double contrast technique improves mucosal visualisation by using gas to distend the barium-coated intestinal surface. Contrast studies are useful for detecting filling defects, such as tumours, strictures, ulcers and motility disorders, but are inferior to endoscopic procedures and more sophisticated cross-sectional imaging techniques, such as computed tomography and magnetic resonance imaging. The major uses and limitations of various contrast studies are shown in Box 21.3 and Figure 21.12.

### Contrast studies

X-rays with contrast medium are usually performed to assess not only anatomical abnormalities but also motility. Barium sulphate provides good mucosal coating and excellent opacification but can precipitate impaction proximal to an obstructive lesion. Water-soluble contrast is used to opacify bowel prior to abdominal computed tomography and in cases of suspected perforation.

### Limitations
- Low sensitivity for small lesions
- Little functional information
- Operator-dependent
- Gas and obesity may obscure view

### Endoscopy

#### Ultrasound, computed tomography and magnetic resonance imaging
Ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) are key tests in the evaluation of intra-abdominal disease. They are non-invasive and offer detailed images of the abdominal contents. Fluorodeoxyglucose–positron emission tomography (FDG-PET) is increasingly used in the staging of malignancies and images may be fused with CT to enhance localisation. Their main applications are summarised in Box 21.4 and Figure 21.13.

#### Videoendoscopy
Videoendoscopes provide high-definition imaging and accessories can be passed down the endoscope to allow both diagnostic and therapeutic procedures, some of which are illustrated in Figure 21.14. Endoscopes with magnifying lenses allow almost microscopic detail to be observed, and imaging modalities, such as confocal endomicroscopy, autofluorescence and ‘narrow-band imaging’, are increasingly used to detect subtle abnormalities not visible by standard ‘white light’ endoscopy.

#### Upper gastrointestinal endoscopy
This is performed under light intravenous benzodiazepine sedation, or using only local anaesthetic throat spray after the patient has fasted for at least 4 hours. With the patient in the left lateral position, the entire oesophagus (excluding pharynx), stomach and first two parts of duodenum can be seen.

#### Indications, contraindications and complications are given in Box 21.5.

### Endoscopic ultrasound
Endoscopic ultrasound (EUS) combines endoscopy with intraluminal ultrasonography using a high-frequency transducer to produce high-resolution ultrasound images. This allows visualisation through the wall of the gastrointestinal tract and into surrounding tissues, e.g. the pancreas or lymph nodes. It can therefore be used to perform fine needle aspiration or biopsy of mass lesions. EUS is helpful in the diagnosis of pancreatic tumours, chronic pancreatitis, pancreatic cysts, cholangiocarcinoma, common bile duct stones, ampullary lesions and submucosal tumours. It also plays an important role in the staging of certain cancers, e.g. those of oesophagus and pancreas. EUS can also be therapeutic, as in drainage of pancreatic fluid collections and coeliac plexus block for pain management. Possible complications of EUS include bleeding, infection, cardiopulmonary events and perforation.

#### Capsule endoscopy
Capsule endoscopy (Fig. 21.15) uses a capsule containing an imaging device, battery, transmitter and antenna; as it traverses the small intestine, it transmits images to a battery-powered recorder worn on a belt round the patient’s waist. After approximately 8 hours, the capsule is excreted. Images from the capsule are analysed as a video sequence and it is usually possible to localise the segment of small bowel in which lesions are seen. Abnormalities detected usually require enteroscopy.
Investigation of gastrointestinal disease

Control of bleeding
- Injection sclerotherapy
- Diathermy
- Variceal ligation
- Laser therapy
- Endoscopic clipping

Treatment of tumours
- Laser therapy
- Polypectomy
- Photodynamic therapy/radiofrequency ablation
- Endoscopic mucosal resection
- Endoscopic submucosal dissection (ESD)

Treatment of strictures
- Stent insertion
- Balloon dilatation
- Bouginage

Management of biliary and pancreatic disease
- Sphincterotomy
- Basket retrieval
- Stent insertion
- Pseudocyst drainage

Fig. 21.14 Examples of therapeutic techniques in endoscopy.

21.5 Upper gastrointestinal endoscopy

Indications
- Dyspepsia in patients >55 years of age or with alarm symptoms
- Atypical chest pain
- Dysphagia
- Vomiting
- Weight loss
- Acute or chronic gastrointestinal bleeding
- Screening for oesophageal varices in chronic liver disease
- Abnormal CT scan or barium meal
- Duodenal biopsies in the investigation of malabsorption and confirmation of a diagnosis of coeliac disease prior to commencement of gluten-free diet
- Therapy, including treatment of bleeding lesions, banding/injection of varices, dilatation of strictures, insertion of stents, placement of percutaneous gastrostomies, ablation of Barrett’s oesophagus and resection of high-grade dysplastic lesions and early neoplasia in the upper gastrointestinal tract

Contraindications
- Severe shock
- Recent myocardial infarction, unstable angina, cardiac arrhythmia*
- Severe respiratory disease*
- Atlantoaxial subluxation*
- Possible visceral perforation

Complications
- Cardiorespiratory depression due to sedation
- Aspiration pneumonia
- Perforation

*These are ‘relative’ contraindications; in experienced hands, endoscopy can be safely performed.

Fig. 21.15 Wireless capsule endoscopy.
A Examples of capsules  B Capsule endoscopy image of bleeding jejunal vascular malformation. A, Courtesy of Given Imaging.
for confirmation and therapy. Indications, contraindications and complications are listed in Box 21.6.

**Double balloon enteroscopy**

While endoscopy can reach the proximal small intestine in most patients, a technique called double balloon enteroscopy is also available, which uses a long endoscope with a flexible overtube. Sequential and repeated inflation and deflation of balloons on the tip of the overtube and enteroscope allow the operator to push and pull along the entire length of the small intestine to the terminal ileum, in order to diagnose or treat small bowel lesions detected by capsule endoscopy or other imaging modalities. Indications, contraindications and complications are listed in Box 21.7.

**Sigmoidoscopy and colonoscopy**

Sigmoidoscopy can be carried out either in the outpatient clinic using a 20 cm rigid plastic sigmoidoscope or in the endoscopy suite using a 60 cm flexible colonoscope following bowel preparation. When sigmoidoscopy is combined with proctoscopy, accurate detection of haemorrhoids, ulcerative colitis and distal colorectal neoplasia is possible. After full bowel cleansing, it is possible to examine the entire colon and the terminal ileum using a longer colonoscope. Indications, contraindications and complications of colonoscopy are listed in Box 21.8.

**Magnetic resonance cholangiopancreatography**

Magnetic resonance cholangiopancreatography (MRCP) has largely replaced endoscopic retrograde cholangiopancreatography (ERCP) in the evaluation of obstructive jaundice since it produces comparable images of the biliary tree and pancreas, providing information that complements that obtained from CT and endoscopic ultrasound examination (EUS).

**Endoscopic retrograde cholangiopancreatography**

Using a side-viewing duodenoscope, it is possible to cannulate the main pancreatic duct and common bile duct. Nowadays, ERCP is used mainly in the treatment of a range of biliary and pancreatic diseases that have been identified by other imaging techniques such as MRCP, EUS and CT. Indications for and risks of ERCP are listed in Box 21.10.

**Histology**

Biopsy material obtained endoscopically or percutaneously can provide useful information (Box 21.11).
Investigation of gastrointestinal disease

21.10 Endoscopic retrograde cholangiopancreatography

Indications
Diagnostic
• Biliary or pancreatic disease where other imaging is equivocal or contraindicated
• Ampullary biopsy or biliary cytology
Therapeutic
• Biliary disease:
  Removal of common bile duct calculi*
  Palliation of malignant biliary obstruction
  Management of biliary leaks/damage complicating surgery
  Dilatation of benign stricture
  Primary sclerosing cholangitis
• Pancreatic disease:
  Drainage of pancreatic pseudocysts and fistulae
  Removal of pancreatic calcification (selected cases)

Contraindications
• Severe cardiopulmonary comorbidity
• Coagulopathy

Complications
• Occur in 5–10% with a 30-day mortality of 0.5–1%

General
• As for upper endoscopy

Specific
• Biliary disease:
  Bleeding following sphincterotomy
  Cholangitis (if biliary obstruction is not relieved by ERCP)
  Gallstone impaction
• Pancreatic disease:
  Acute pancreatitis
  Infection of pseudocyst

*Laparoscopic surgery is preferred in fit individuals who also require cholecystectomy.

21.11 Reasons for biopsy or cytological examination

• Suspected malignant lesions
• Assessment of mucosal abnormalities
• Diagnosis of infection (Candida, Helicobacter pylori, Giardia lamblia)
• Analysis of genetic mutations

Tests of infection

Bacterial cultures

Stool cultures are essential in the investigation of diarrhoea, especially when it is acute or bloody, in order to identify pathogenic organisms (Ch. 11).

Serology

Detection of antibodies plays a limited role in the diagnosis of gastrointestinal infection caused by organisms such as Helicobacter pylori, Salmonella species and Entamoeba histolytica.

Breath tests

Non-invasive breath tests for H. pylori infection are discussed on page 800 and breath tests for suspected small intestinal bacterial overgrowth on page 808.

Tests of function

A number of dynamic tests can be used to investigate aspects of gut function, including digestion, absorption, inflammation and epithelial permeability. Some of the more common ones are listed in Box 21.12. In the assessment of suspected malabsorption, blood tests (full blood count, erythrocyte sedimentation rate (ESR), and measurement of C-reactive protein (CRP), folate, vitamin B₁₂, *Laparoscopic surgery is preferred in fit individuals who also require cholecystectomy.

21.12 Tests of gastrointestinal function

<table>

<td>Immunoenzyme of pancreatic enzymes on stool sample</td>
<td>Simple, quick and avoids urine collection. Does not detect mild disease</td>
</tr>
<tr>
<td>Mucosal inflammation/permeability</td>
<td>Faecal calprotectin</td>
<td>A protein secreted non-specifically by neutrophils into the colon in response to inflammation or neoplasia</td>
<td>Useful screening test for gastrointestinal inflammation and for monitoring patients with Crohn’s disease and ulcerative colitis. Poor sensitivity for cancer</td>
</tr>
</tbody>
</table>

(⁷⁵SeHCAT = ⁷⁵Se-homocholic acid taurine)
iron status, albumin, calcium and phosphate) are essential, and endoscopy is undertaken to obtain mucosal biopsies. Faecal calprotectin is very sensitive at detecting mucosal inflammation.

### Oesophageal motility

A barium swallow can give useful information about oesophageal motility. Videofluoroscopy, with joint assessment by a speech and language therapist and a radiologist, may be necessary in difficult cases. Oesophageal manometry (see Fig. 21.1), often in conjunction with 24-hour pH measurements, is of value in diagnosing cases of refractory gastro-oesophageal reflux, achalasia and non-cardiac chest pain. Oesophageal impedance testing is useful for detecting non-acid or gas reflux events, especially in patients with atypical symptoms or those who respond poorly to acid suppression.

### Gastric emptying

This involves administering a test meal containing solids and liquids labelled with different radioisotopes and measuring the amount retained in the stomach afterwards (Box 21.13). It is useful in the investigation of suspected delayed gastric emptying (gastroparesis) when other studies are normal.

### Colonic and anorectal motility

A plain abdominal X-ray taken on day 5 after ingestion of different-shaped inert plastic pellets on days 1–3 gives an estimate of whole-gut transit time. The test is useful in the evaluation of chronic constipation, when the position of any retained pellets can be observed, and helps to differentiate cases of slow transit from those due to obstructed defecation. The mechanism of defecation and anorectal function can be assessed by anorectal manometry, electrophysiological tests and defecating proctography.

### Radioisotope tests

Many different radioisotope tests are used (Box 21.13). In some, structural information is obtained, such as the localisation of a Meckel’s diverticulum. Others provide functional information, such as the rate of gastric emptying or ability to reabsorb bile acids. Yet others are tests of infection and rely on the presence of bacteria to hydrolyse a radio-labelled test substance followed by detection of the radioisotope in expired air, such as the urea breath test for *H. pylori*.

### Gut hormone testing

Excess gut hormone secretion by some gastrointestinal and pancreatic neuro-endocrine tumours can be assessed by measuring levels in blood. Commonly measured hormones include gastrin, somatostatin, vasoactive intestinal polypeptide (VIP) and pancreatic polypeptide.

### Presenting problems in gastrointestinal disease

#### Dysphagia

Dysphagia is defined as difficulty in swallowing. It may coexist with heartburn or vomiting but should be distinguished from both globus sensation (in which anxious people feel a lump in the throat without organic cause) and odynophagia (pain during swallowing, usually from gastro-oesophageal reflux or candidiasis). Dysphagia can occur due to problems in the oropharynx or oesophagus (Fig. 21.16). Oropharyngeal disorders affect the initiation of swallowing at the pharynx and upper oesophageal sphincter. The patient has difficulty initiating swallowing and complains of choking, nasal regurgitation or tracheal aspiration. Drooling, dysarthria, hoarseness and cranial nerve or other neurological signs may be present. Oesophageal disorders cause dysphagia by obstructing the lumen or by affecting motility. Patients with oesophageal disease complain of food ‘sticking’ after swallowing, although the level at which this is felt correlates poorly with the true site of obstruction. Swallowing of liquids is normal until strictures become extreme.

### Investigations

Dysphagia should always be investigated urgently. Endoscopy is the investigation of choice because it allows biopsy and dilatation of strictures. Even if the appearances are normal, biopsies should be taken to look for eosinophilic oesophagitis. If no abnormality is found, then barium swallow with videofluoroscopic swallowing assessment is indicated to detect major motility disorders. In some cases, oesophageal manometry is required. High-resolution manometry allows accurate classification of abnormalities. Figure 21.16 summarises a diagnostic approach to dysphagia and lists the major causes.

Dyspepsia

Dyspepsia describes symptoms such as discomfort, bloating and nausea, which are thought to originate from the upper gastrointestinal tract. There are many causes (Box 21.14), including some arising outside the digestive system. Heartburn and other ‘reflux’ symptoms are separate entities and are considered elsewhere. Although symptoms often correlate poorly with the underlying diagnosis, a careful history is important to detect ‘alarm’ features requiring urgent investigation (Box 21.15) and to detect atypical symptoms that might be due to problems outside the gastrointestinal tract.

Dyspepsia affects up to 80% of the population at some time in life and most patients have no serious underlying disease. People who present with new dyspepsia at an age of more than 55 years and younger patients unresponsive to empirical treatment require investigation to exclude serious disease. An algorithm for the investigation of dyspepsia is outlined in Figure 21.17.

Heartburn and regurgitation

Heartburn describes retrosternal, burning discomfort, often rising up into the chest and sometimes accompanied by regurgitation of acidic or bitter fluid into the throat. These symptoms often occur after meals, on lying down or with bending, straining or heavy lifting. They are classical symptoms of gastro-oesophageal reflux but up to 50% of patients present with other symptoms, such as chest pain, belching, halitosis, chronic cough or sore throats. In young patients with typical symptoms and a good response to dietary changes, antacids or acid suppression investigation is not required, but in patients over 55 years of age and those with alarm symptoms or atypical features urgent endoscopy is necessary.
Fig. 21.17 Investigation of dyspepsia.

Vomiting

Vomiting is a complex reflex involving both autonomic and somatic neural pathways. Synchronous contraction of the diaphragm, intercostal muscles and abdominal muscles raises intra-abdominal pressure and, combined with relaxation of the lower oesophageal sphincter, results in forcible ejection of gastric contents. It is important to distinguish true vomiting from regurgitation and to elicit whether the vomiting is acute or chronic (recurrent), as the underlying causes may differ. The major causes are shown in Figure 21.18.

Gastrointestinal bleeding

Acute upper gastrointestinal haemorrhage

This is the most common gastrointestinal emergency, accounting for 50–170 admissions to hospital per 100 000 of the population each year in the UK. The mortality of patients admitted to hospital is about 10% but there is some evidence that outcome is better when individuals are treated in specialised units. Risk scoring systems have been developed to stratify the risk of needing endoscopic therapy or of having a poor outcome (Box 21.16). The advantage of the Blatchford score is that it may be used before endoscopy to predict the need for intervention to treat bleeding. Low scores (2 or less) are associated with a very low risk of adverse outcome. The common causes are shown in Figure 21.19.

Clinical assessment

Haematemesis is red with clots when bleeding is rapid and profuse, or black (‘coffee grounds’) when less severe. Syncope may occur and is caused by hypotension from intravascular volume depletion. Symptoms of anaemia suggest chronic bleeding. Melaena is the passage of black, tarry stools containing altered blood; it is usually caused by bleeding from the upper gastrointestinal tract, although haemorrhage from the right side of the colon is occasionally responsible. The characteristic colour and smell are the result of the action of digestive enzymes and of bacteria on haemoglobin. Severe acute upper gastrointestinal bleeding can sometimes cause maroon or bright red stool.
Management
The principles of emergency management of non-variceal bleeding are discussed in detail below. Management of variceal bleeding is discussed on page 869.

1. Intravenous access
The first step is to gain intravenous access using at least one large-bore cannula.

2. Initial clinical assessment
- Define circulatory status. Severe bleeding causes tachycardia, hypotension and oliguria. The patient is cold and sweating, and may be agitated.
- Seek evidence of liver disease (p. 846). Jaundice, cutaneous stigmata, hepatosplenomegaly and ascites may be present in decompensated cirrhosis.
- Identify comorbidity. The presence of cardiorespiratory, cerebrovascular or renal disease is important, both because these may be worsened by acute bleeding and because they increase the hazards of endoscopy and surgical operations.

These factors can be combined using the Blatchford score (Box 21.16), which can be calculated at the bedside. A score of 2 or less is associated with a good prognosis, while progressively higher scores are associated with poorer outcomes.

3. Basic investigations
- Full blood count. Chronic or subacute bleeding leads to anaemia but the haemoglobin concentration may be normal after sudden, major bleeding until haemodilution occurs. Thrombocytopenia may be a clue to the presence of hypersplenism in chronic liver disease.
- Urea and electrolytes. This test may show evidence of renal failure. The blood urea rises as the absorbed products of luminal blood are metabolised by the liver; an elevated blood urea with normal creatinine concentration implies severe bleeding.
- Liver function tests. These may show evidence of chronic liver disease.
- Prothrombin time. Check when there is a clinical suggestion of liver disease or patients are anticoagulated.
- Cross-matching. At least 2 units of blood should be cross-matched if a significant bleed is suspected.

</table>

**Fig. 21.19 Causes of acute upper gastrointestinal haemorrhage.** Frequency is given in parentheses. (NSAIDs = non-steroidal anti-inflammatory drugs)
4. Resuscitation

Intravenous crystalloid fluids should be given to raise the blood pressure, and blood should be transfused when the patient is actively bleeding with low blood pressure and tachycardia. Comorbidities should be managed as appropriate. Patients with suspected chronic liver disease should receive broad-spectrum antibiotics.

5. Oxygen

This should be given to all patients in shock.

6. Endoscopy

This should be carried out after adequate resuscitation, ideally within 24 hours, and will yield a diagnosis in 80% of cases. Patients who are found to have major endoscopic stigmata of recent haemorrhage (Fig. 21.20) can be treated endoscopically using a thermal or mechanical modality, such as a ‘heater probe’ or endoscopic clips, combined with injection of dilute adrenaline (epinephrine) into the bleeding point (‘dual therapy’). A biologically inert haemostatic mineral powder (TC325, ‘haemospray’) can be used as rescue therapy when standard therapy fails. This may stop active bleeding and, combined with intravenous proton pump inhibitor (PPI) therapy, may prevent rebleeding, thus avoiding the need for surgery. Patients found to have bled from varices should be treated by band ligation (p. 870); if this fails, balloon tamponade is another option, while arrangements are made for a transjugular intrahepatic portosystemic shunt (TIPSS).

7. Monitoring

Patients should be closely observed, with hourly measurements of pulse, blood pressure and urine output.

8. Surgery

Surgery is indicated when endoscopic haemostasis fails to stop active bleeding and if rebleeding occurs on one occasion in an elderly or frail patient, or twice in a younger, fitter patient. If available, angiographic embolisation is an effective alternative to surgery in frail patients.

The choice of operation depends on the site and diagnosis of the bleeding lesion. Duodenal ulcers are treated by under-running, with or without pyloroplasty. Under-running for gastric ulcers can also be carried out (a biopsy must be taken to exclude carcinoma). Local excision may be performed, but when neither is possible, partial gastrectomy is required.

9. Eradication

Following treatment for ulcer bleeding, all patients should avoid non-steroidal anti-inflammatory drugs (NSAIDs) and those who test positive for H. pylori infection should receive eradication therapy (p. 800). Successful eradication should be confirmed by urea breath or faecal antigen testing.

Lower gastrointestinal bleeding

This may be caused by haemorrhage from the colon, anal canal or small bowel. It is useful to distinguish those patients who present with profuse, acute bleeding from those who present with chronic or subacute bleeding of lesser severity (Box 21.17).

Severe acute lower gastrointestinal bleeding

This presents with profuse red or maroon diarrhoea and with shock. Diverticular disease is the most common cause and is often due to erosion of an artery within the mouth of a diverticulum. Bleeding almost always stops spontaneously, but if it does not, the diseased segment of colon should be resected after confirmation of the site by angiography or colonoscopy. Angiodysplasia is a disease of the elderly, in which vascular malformations develop in the proximal colon. Bleeding can be acute and profuse; it usually

![Fig. 21.20 Major stigmata of recent haemorrhage and endoscopic treatment.](image-url)

**A** Active bleeding from a duodenal ulcer. **B** Haemostasis is achieved after endoscopic injection of adrenaline (epinephrine) and application of a heater probe.
stops spontaneously but commonly recurs. Diagnosis is often difficult. Colonoscopy may reveal characteristic vascular spots and, in the acute phase, visceral angiography can show bleeding into the intestinal lumen and an abnormal large, draining vein. In some patients, diagnosis is achieved only by laparotomy with on-table colonoscopy. The treatment of choice is endoscopic thermal ablation but resection of the affected bowel may be required if bleeding continues. Bowel ischaemia due to occlusion of the inferior mesenteric artery can present with abdominal colic and rectal bleeding. It should be considered in patients (particularly the elderly) who have evidence of generalised atherosclerosis. The diagnosis is made at colonoscopy. Resection is required only in the presence of peritonitis. Meckel’s diverticulum with ectopic gastric epithelium may ulcerate and erode into a major artery. The diagnosis should be considered in children or adolescents who present with profuse or recurrent lower gastrointestinal bleeding. A Meckel’s 99mTc-pertechnetate scan is sometimes positive but the diagnosis is commonly made only by laparotomy, at which time the diverticulum is excised.

**Subacute or chronic lower gastrointestinal bleeding**

This can occur at all ages and is usually due to haemorrhoids or anal fissure. Haemorrhoidal bleeding is bright red and occurs during or after defecation. Proctoscopy can be used to make the diagnosis, but subjects who have altered bowel habit and those who present over the age of 40 years should undergo colonoscopy to exclude coexisting colorectal cancer. Anal fissure should be suspected when fresh rectal bleeding and anal pain occur during defecation.

**Major gastrointestinal bleeding of unknown cause**

In some patients who present with major gastrointestinal bleeding, upper endoscopy and colonoscopy fail to reveal a diagnosis. When severe life-threatening bleeding continues, urgent CT mesenteric angiography is indicated. This will usually identify the site if the bleeding rate exceeds 1 mL/min and then formal angiographic embolisation can often stop the bleeding. If angiography is negative or bleeding is less severe, push or double balloon enteroscopy can visualise the small intestine (Fig. 21.21) and treat the bleeding source. Wireless capsule endoscopy is often used to define a source of bleeding prior to enteroscopy. When all else fails, laparotomy with on-table endoscopy is indicated.

**Chronic occult gastrointestinal bleeding**

In this context, occult means that blood or its breakdown products are present in the stool but cannot be seen by the naked eye. Occult bleeding may reach 200 mL per day and cause iron deficiency anaemia. Any cause of gastrointestinal bleeding may be responsible but the most important is colorectal cancer, particularly carcinoma of the caecum, which may produce no gastrointestinal symptoms. In clinical practice, investigation of the upper and lower gastrointestinal tract should be considered whenever a patient presents with unexplained iron deficiency anaemia. Testing the stool for the presence of blood is unnecessary and should not influence whether or not the gastrointestinal tract is imaged because bleeding from tumours is often intermittent and a negative faecal occult blood (FOB) test does not exclude the diagnosis. The only value of FOB testing is as a means of population screening for colonic neoplasm in asymptomatic individuals (p. 832).

**Diarrhoea**

Diarrhoea is defined as the passage of more than 200 g of stool daily and measurement of stool volume is helpful in confirming this. The most severe symptom in many patients is urgency of defecation, and faecal incontinence is a common event in acute and chronic diarrhoeal illnesses.

**Acute diarrhoea**

This is extremely common and is usually caused by faecal–oral transmission of bacteria or their toxins, viruses or parasites (Ch. 11). Infective diarrhoea is usually short-lived and patients who present with a history of diarrhoea lasting more than 10 days rarely have an infective cause. A variety of drugs, including antibiotics, cytotoxic drugs, PPIs and NSAIDs, may be responsible.

**Chronic or relapsing diarrhoea**

The most common cause is irritable bowel syndrome (p. 824), which can present with increased frequency of defecation and loose, watery or pelletty stools. Diarrhoea rarely occurs at night and is most severe before and after breakfast. At other times, the patient is constipated and there are other characteristic symptoms of irritable bowel syndrome. The stool often contains mucus but never blood, and 24-hour stool volume is less than 200 g. Chronic diarrhoea can be categorised as being caused by disease of the colon or small bowel, or to malabsorption (Box 21.18). Clinical presentation, examination of the stool, routine blood tests and imaging reveal a diagnosis in many cases. A series of negative investigations usually implies irritable bowel syndrome but some patients clearly have organic disease and need more extensive investigations.

**Malabsorption**

Diarrhoea and weight loss in patients with a normal diet are likely to be caused by malabsorption. The symptoms are diverse in nature and variable in severity. A few patients have apparently normal bowel habit but diarrhoea is usual and may be watery and voluminous. Bulky, pale and offensive stools that float in the toilet (steatorrhoea) signify fat malabsorption. Abdominal
Pathophysiology

Malabsorption results from abnormalities of the three processes that are essential to normal digestion:

- **Intraluminal maldigestion** occurs when deficiency of bile or pancreatic enzymes results in inadequate solubilisation.

**Clinical features**

- Blood and mucus in stool
- Cramping lower abdominal pain

**Malabsorption**

- Steatorrhoea
- Undigested food in the stool
- Weight loss and nutritional disturbances

**Small bowel**

- Large-volume, watery stool
- Abdominal bloating
- Cramping mid-abdominal pain

**Some causes**

- Inflammatory bowel disease
- Microscopic colitis
- Neoplasia
- Ischaemia
- Irritable bowel syndrome

- Pancreatic:
  - Chronic pancreatitis
  - Cancer of pancreas
  - Cystic fibrosis
- Enteropathy:
  - Coeliac disease
  - Tropical sprue
  - Lymphoma
  - Lymphangiectasia

- Crohn’s disease
- VIPoma
- Drug-induced:
  - NSAIDs
  - Aminosalicylates
  - SSRIs

**Investigations**

- Faecal calprotectin
- Ileocolonoscopy with biopsies
- Faecal elastase
- Ultrasound, CT and MRCP
- Small-bowel biopsy
- Barium follow-through or small-bowel MRI

(CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; NSAIDs = non-steroidal anti-inflammatory drugs; SSRIs = selective serotonin re-uptake inhibitors; VIP = vasoactive intestinal polypeptide)

**Fig. 21.22** Possible physical consequences of malabsorption.

Distension, borborygmi, cramps, weight loss and undigested food in the stool may be present. Some patients complain only of malaise and lethargy. In others, symptoms related to deficiencies of specific vitamins, trace elements and minerals may occur (Fig. 21.22).
and hydrolysis of nutrients. Fat and protein malabsorption results. This may also occur with small bowel bacterial overgrowth.

- **Mucosal malabsorption** results from small bowel resection or conditions that damage the small intestinal epithelium, thereby diminishing the surface area for absorption and depleting brush border enzyme activity.
- ‘Post-mucosal’ lymphatic obstruction prevents the uptake and transport of absorbed lipids into lymphatic vessels. Increased pressure in these vessels results in leakage into the intestinal lumen, leading to protein-losing enteropathy.

**Investigations**

Investigations should be performed both to confirm the presence of malabsorption and to determine the underlying cause. Routine blood tests may show one or more of the abnormalities listed in Box 21.19. Tests to confirm fat and protein malabsorption should be performed, as described on page 777. An approach to the investigation of malabsorption is shown in Figure 21.23.

**Weight loss**

Weight loss may be physiological, due to dieting, exercise, starvation, or the decreased nutritional intake that accompanies old age. Weight loss of more than 3 kg over 6 months is significant and often indicates the presence of an underlying disease. Hospital and general practice weight records may be valuable in confirming that weight loss has occurred, as may reweighing patients at intervals; sometimes weight is regained or stabilises in those with no obvious cause. Pathological weight loss can be due to psychiatric illness, systemic disease, gastrointestinal causes or advanced disease of many organ systems (Fig. 21.24).

**Physiological causes**

Weight loss can occur in the absence of serious disease in healthy individuals who have changes in physical activity or social circumstances. It may be difficult to be sure of this diagnosis in older patients, when the dietary history may be unreliable, and professional help from a dietitian is often valuable under these circumstances.

**Psychiatric illness**

Features of anorexia nervosa (p. 1203), bulimia (p. 1204) and affective disorders (p. 1199) may be apparent only after formal psychiatric input. Alcoholic patients lose weight as a consequence of self-neglect and poor dietary intake. Depression may cause weight loss.

**Systemic disease**

Chronic infections, including tuberculosis (p. 588), recurrent urinary or chest infections, and a range of parasitic and protozoan infections (Ch. 11), should be considered. A history of foreign travel, high-risk activities and specific features, such as fever, night sweats, rigors, productive cough and dysuria, must be sought. Promiscuous sexual activity and drug misuse suggest HIV-related illness (Ch. 12). Weight loss is a late feature of disseminated malignancy, but by the time the patient presents, other features of cancer are often present. Chronic inflammatory diseases, such as rheumatoid arthritis (p. 1021) and polymyalgia rheumatica (p. 1042), are often associated with weight loss.

**Gastrointestinal disease**

Almost any disease of the gastrointestinal tract can cause weight loss. Dysphagia and gastric outflow obstruction (pp. 778 and 801) cause weight loss by reducing food intake. Malignancy at any site may cause weight loss by mechanical obstruction, anorexia or cytokine-mediated systemic effects. Malabsorption from pancreatic diseases (p. 837) or small bowel causes may lead to profound weight loss with specific nutritional deficiencies (p. 704). Inflammatory diseases, such as Crohn’s disease or ulcerative colitis (p. 813), cause anorexia, fear of eating and loss of protein, blood and nutrients from the gut.

**Metabolic disorders and miscellaneous causes**

Weight loss may occur in association with metabolic disorders, as well as end-stage respiratory and cardiac disease.
In cases where the cause of weight loss is not obvious after thorough history taking and physical examination, or where an existing condition is considered unlikely, the following investigations are indicated: urinalysis for glucose, protein and blood; blood tests, including liver function tests, random blood glucose and thyroid function tests; CRP and ESR (may be raised in unsuspected infections, such as tuberculosis, connective tissue disorders and malignancy); and faecal calprotectin. Sometimes invasive tests, such as bone marrow aspiration or liver biopsy, may be necessary to identify conditions like cryptic miliary tuberculosis (p. 588). Rarely, abdominal and pelvic imaging by CT may be required, but before embarking on invasive or very costly investigations it is always worth revisiting the patient’s history and reweighing at intervals.

**Constipation**

Constipation is defined as infrequent passage of hard stools. Patients may also complain of straining, a sensation of incomplete evacuation and either perianal or abdominal discomfort. Constipation may occur in many gastrointestinal and other medical disorders (Box 21.20).

**Clinical assessment and management**

The onset, duration and characteristics are important; for example, a neonatal onset suggests Hirschsprung’s disease, while a recent change in bowel activity in middle age should raise the suspicion of an organic disorder, such as colonic carcinoma. The presence of rectal bleeding, pain and weight loss is important, as are excessive

---

**21.20 Causes of constipation**

**Gastrointestinal causes**

- **Dietary**
  - Lack of fibre and/or fluid intake

- **Motility**
  - Slow-transit constipation
  - Irritable bowel syndrome
  - Drugs (see below)

- **Structural**
  - Colonic carcinoma
  - Diverticular disease

- **Defecation**
  - Anorectal disease (Crohn’s, fissures, haemorrhoids)

**Non-gastrointestinal causes**

- **Drugs**
  - Opiates
  - Anticholinergics
  - Calcium antagonists

- **Neurological**
  - Multiple sclerosis
  - Spinal cord lesions

- **Metabolic/endocrine**
  - Diabetes mellitus
  - Hypercalcaemia

- **Others**
  - Any serious illness with immobility, especially in the elderly

**Endocrine**

- Type 1 diabetes
- Thyrotoxicosis
- Addison’s disease

**Respiratory**

- Congestive cardiac failure
- Infective endocarditis

**Renal**

- Occult malignancy
- Chronic renal failure
- Salt-losing nephropathy

**Psychosocial**

- Deprivation, starvation
- Eating disorders
- Depression, bipolar illness
- Bereavement
- Chronic pain/sleep deprivation
- Alcoholism

**Gastrointestinal**

- Poor dentition
- Any cause of oral pain, dysphagia
- Malabsorption
- Malignancy at any site
- Inflammatory bowel disease
- Chronic infection
- Cirrhosis

**Chronic infection**

- HIV/AIDS
- Tuberculosis
- Brucellosis
- Gut infestations

**Neurodegenerative**

- Parkinsonism
- Dementia
- Motor neuron disease

**Rheumatological**

- Rheumatoid arthritis
- Mixed connective tissue disease
- Systemic sclerosis
- Systemic lupus erythematosus

**Respiratory**

- Chronic obstructive pulmonary disease
- Pulmonary tuberculosis
- Occult malignancy (especially small-cell carcinoma)
- Empyema

**Cardiac**

- Congestive cardiac failure
- Infective endocarditis

**Renal**

- Occult malignancy
- Chronic renal failure
- Salt-losing nephropathy

**Psychosocial**

- Deprivation, starvation
- Eating disorders
- Depression, bipolar illness
- Bereavement
- Chronic pain/sleep deprivation
- Alcoholism

**Gastrointestinal**

- Poor dentition
- Any cause of oral pain, dysphagia
- Malabsorption
- Malignancy at any site
- Inflammatory bowel disease
- Chronic infection
- Cirrhosis

**Chronic infection**

- HIV/AIDS
- Tuberculosis
- Brucellosis
- Gut infestations

**Neurodegenerative**

- Parkinsonism
- Dementia
- Motor neuron disease

**Endocrine**

- Type 1 diabetes
- Thyrotoxicosis
- Addison’s disease

**Respiratory**

- Congestive cardiac failure
- Infective endocarditis

**Renal**

- Occult malignancy
- Chronic renal failure
- Salt-losing nephropathy

**Psychosocial**

- Deprivation, starvation
- Eating disorders
- Depression, bipolar illness
- Bereavement
- Chronic pain/sleep deprivation
- Alcoholism

**Gastrointestinal**

- Poor dentition
- Any cause of oral pain, dysphagia
- Malabsorption
- Malignancy at any site
- Inflammatory bowel disease
- Chronic infection
- Cirrhosis

**Chronic infection**

- HIV/AIDS
- Tuberculosis
- Brucellosis
- Gut infestations
straining, symptoms suggestive of irritable bowel syndrome, a history of childhood constipation and emotional distress.

Careful examination contributes more to the diagnosis than extensive investigation. A search should be made for general medical disorders, as well as signs of intestinal obstruction. Neurological disorders, especially spinal cord lesions, should be sought. Perineal inspection and rectal examination are essential and may reveal abnormalities of the pelvic floor (abnormal descent, impaired sensation), anal canal or rectum (masses, faecal impaction, prolapse).

It is neither possible nor appropriate to investigate every person with constipation. Most respond to increased fluid intake, dietary fibre supplementation, exercise and the judicious use of laxatives. Middle-aged or elderly patients with a short history or worrying symptoms (rectal bleeding, pain or weight loss) must be investigated promptly, by either barium enema or colonoscopy. For those with simple constipation, investigation will usually proceed along the lines described below.

Initial visit
Digital rectal examination, proctoscopy and sigmoidoscopy (to detect anorectal disease), routine biochemistry, including serum calcium and thyroid function tests, and a full blood count should be carried out. If these are normal, a 1-month trial of dietary fibre and/or laxatives is justified.

Next visit
If symptoms persist, then examination of the colon by barium enema or CT colonography is indicated to look for structural disease.

Further investigation
If no cause is found and disabling symptoms are present, then specialist referral for investigation of possible dysmotility may be necessary. The problem may be one of infrequent desire to defecate (‘slow transit’) or else may result from neuromuscular incoordination and excessive straining (‘functional obstructive defecation’, p. 803). Intestinal marker studies, anorectal manometry, electrophysiological studies and magnetic resonance proctography can all be used to define the problem.

Abdominal pain
There are four types of abdominal pain:

- **Visceral.** Gut organs are insensitive to stimuli such as burning and cutting but are sensitive to distension, contraction, twisting and stretching. Pain from unpaired structures is usually, but not always, felt in the midline.
- **Parietal.** The parietal peritoneum is innervated by somatic nerves and its involvement by inflammation, infection or neoplasia causes sharp, well-localised and lateralised pain.
- **Referred pain.** Gallbladder pain, for example, may be referred to the back or shoulder tip.
- **Psychogenic.** Cultural, emotional and psychosocial factors influence everyone’s experience of pain. In some patients, no organic cause can be found despite investigation, and psychogenic causes (depression or somatisation disorder) may be responsible (pp. 1198 and 1202).

The acute abdomen
This accounts for approximately 50% of all urgent admissions to general surgical units. The acute abdomen is a consequence of one or more pathological processes (Box 21.21):

- **Inflammation.** Pain develops gradually, usually over several hours. It is initially rather diffuse until the parietal peritoneum is involved, when it becomes localised. Movement exacerbates the pain; abdominal rigidity and guarding occur.
- **Perforation.** When a viscus perforates, pain starts abruptly; it is severe and leads to generalised peritonitis.
- **Obstruction.** Pain is colicky, with spasms that cause the patient to writhe around and double up. Colicky pain that does not disappear between spasms suggests complicating inflammation.

Initial clinical assessment
If there are signs of peritonitis (guarding and rebound tenderness with rigidity), the patient should be resuscitated with oxygen, intravenous fluids and antibiotics. In other circumstances, further investigations are required (Fig. 21.25).

Investigations
Patients should have a full blood count, urea and electrolytes, glucose and amylase taken to look for evidence of dehydration, leucocytosis and pancreatitis. Urinalysis is useful in suspected renal colic and pyelonephritis. An erect chest X-ray may show air under the diaphragm, suggestive of perforation, and a plain abdominal film may show evidence of obstruction or ileus (see Fig. 21.11). An abdominal ultrasound may help if gallstones or renal stones are suspected. Ultrasonography is also useful in the detection of free fluid and any possible intra-abdominal abscess. Contrast studies, by either mouth or anus, are useful in the further evaluation of intestinal obstruction, and essential in the differentiation of pseudo-obstruction from mechanical large-bowel obstruction. Other investigations commonly used include CT (seeking evidence of pancreatitis, retroperitoneal collections or masses, including an aortic aneurysm or renal calculi) and angiography (mesenteric ischaemia).

Diagnostic laparotomy should be considered when the diagnosis has not been revealed by other investigations. All patients must be carefully and regularly re-assessed (every 2–4 hours) so that any change in condition that might alter both the suspected diagnosis and clinical decision can be observed and acted on early.

Management
The general approach is to close perforations, treat inflammatory conditions with antibiotics or resection, and relieve obstructions. The speed of intervention and the necessity for surgery depend on the organ that is involved and on a number of other factors.
Treatment. The appendix can be removed through a conventional right iliac fossa skin crease incision or by laparoscopic techniques.

**Acute cholecystitis**

This can be successfully treated non-operatively but the high risk of recurrent attacks and the low morbidity of surgery have made early laparoscopic cholecystectomy the treatment of choice.

**Acute diverticulitis**

Conservative therapy is standard but if perforation has occurred, resection is advisable. Depending on peritoneal contamination and the state of the patient, primary anastomosis is preferable to a Hartmann’s procedure ( oversew of rectal stump and end-colostomy).

**Small bowel obstruction**

If the cause is obvious and surgery inevitable (such as with a strangulated hernia), an early operation is appropriate. If the suspected cause is adhesions from previous surgery, only those patients who do not resolve within the first 48 hours or who develop signs of strangulation (colicky pain becoming constant, peritonitis, tachycardia, fever, leucocytosis) should have surgery.

---

**Fig. 21.25** Management of acute abdominal pain: an algorithm.

**21.22 Acute abdominal pain in old age**

- **Presentation:** severity and localisation may blunt with age. Presentation may be atypical, e.g. with delirium, collapse and/or immobility.
- **Cancer:** a more common cause of acute pain in those over 70 years of age than in those under 50 years. Older people with vague abdominal symptoms should therefore be carefully assessed.
- **Non-specific symptoms:** intra-abdominal inflammatory conditions, such as diverticulitis, may present with non-specific symptoms, such as delirium or anorexia and relatively little abdominal tenderness. The reasons for this are not clear but may stem from altered sensory perception.
- **Outcome of abdominal surgery:** determined by how frail the patient is and whether surgery is elective or emergency, rather than by chronological age.

---

of which the presence or absence of peritonitis is the most important. A treatment summary of some of the more common surgical conditions follows.

**Acute appendicitis**

This should be treated by early surgery, since there is a risk of perforation and recurrent attacks with non-operative treatment. The appendix can be removed through a conventional right iliac fossa skin crease incision or by laparoscopic techniques.

**Acute cholecystitis**

This can be successfully treated non-operatively but the high risk of recurrent attacks and the low morbidity of surgery have made early laparoscopic cholecystectomy the treatment of choice.

**Acute diverticulitis**

Conservative therapy is standard but if perforation has occurred, resection is advisable. Depending on peritoneal contamination and the state of the patient, primary anastomosis is preferable to a Hartmann’s procedure ( oversew of rectal stump and end-colostomy).

**Small bowel obstruction**

If the cause is obvious and surgery inevitable (such as with a strangulated hernia), an early operation is appropriate. If the suspected cause is adhesions from previous surgery, only those patients who do not resolve within the first 48 hours or who develop signs of strangulation (colicky pain becoming constant, peritonitis, tachycardia, fever, leucocytosis) should have surgery.
Large bowel obstruction

Pseudo-obstruction should be treated non-operatively. Some patients benefit from colonoscopic decompression but mechanical obstruction merits resection, usually with a primary anastomosis. Differentiation between the two is made by water-soluble contrast enema.

Perforated peptic ulcer

Surgical closure of the perforation is standard practice but some patients without generalised peritonitis can be treated non-operatively once a water-soluble contrast meal has confirmed spontaneous sealing of the perforation. Adequate and aggressive resuscitation with intravenous fluids, antibiotics and analgesia is mandatory before surgery.

For a more detailed discussion of acute abdominal pain, the reader is referred to the sister volume of this text, Principles and Practice of Surgery.

Chronic or recurrent abdominal pain

It is essential to take a detailed history, paying particular attention to features of the pain and any associated symptoms (Boxes 21.23 and 21.24).

Note should be made of the patient’s general demeanour, mood and emotional state, signs of weight loss, fever, jaundice or anaemia. If a thorough abdominal and rectal examination is normal, a careful search should be made for evidence of disease affecting other structures, particularly the vertebral column, spinal cord, lungs and cardiovascular system.

Investigations will depend on the clinical features elicited during the history and examination:

- Endoscopy and ultrasound are indicated for epigastric pain, and for dyspepsia and symptoms suggestive of gallbladder disease.
- Colonoscopy is indicated for patients with altered bowel habit, rectal bleeding or features of obstruction suggesting colonic disease.
- CT or MR angiography should be considered when pain is provoked by food in a patient with widespread atherosclerosis, since this may indicate mesenteric ischaemia.
- Persistent symptoms require exclusion of colonic or small bowel disease. However, young patients with pain relieved by defecation, bloating and alternating bowel habit are likely to have irritable bowel syndrome (p. 824). Simple investigations (blood tests, faecal calprotectin and sigmoidoscopy) are sufficient in the absence of rectal bleeding, weight loss and abnormal physical findings.
- Ultrasound, CT and faecal elastase are required for patients with upper abdominal pain radiating to the back. A history of alcohol misuse, weight loss and diarrhoea suggests chronic pancreatitis or pancreatic cancer.
- Recurrent attacks of pain in the loins radiating to the flanks with urinary symptoms should prompt investigation for renal or ureteric stones by abdominal X-ray, ultrasound and computed tomography of the kidneys, ureters and bladder (CT KUB).
- A past history of psychiatric disturbance, repeated negative investigations or vague symptoms that do not fit any disease or organ pattern suggest a psychological origin for the pain. Careful review of case notes and previous investigations, along with open and honest discussion with the patient, reduces the need for further cycles of unnecessary and invasive tests. Care must always be taken, however, not to miss rare pathology, such as acute intermittent porphyria (p. 378), or atypical presentations of common diseases.

Constant abdominal pain

Patients with chronic pain that is constant or nearly always present usually have features to suggest the underlying diagnosis. No cause will be found in a minority, despite thorough investigation, leading to the diagnosis of ‘chronic functional abdominal pain’. In these patients, there appears to be abnormal CNS processing of normal visceral afferent sensory input and psychosocial factors are often operative (p. 1186); the most important tasks are to provide symptom control, if not relief, and to minimise the effects of the pain on social, personal and occupational life. Patients are best managed in specialised pain clinics where, in addition to psychological support, appropriate use of drugs, including tricyclic antidepressants, gabapentin or pregabalin, ketamine and opioids, may be necessary.
Aphthous ulcers are superficial and painful; they occur in any part of the mouth. Recurrent ulcers afflict up to 30% of the population and are particularly common in women prior to menstruation. The cause is unknown, but in severe cases other causes of oral ulceration must be considered (Box 21.25). Biopsy is occasionally necessary for diagnosis.

Management is with topical glucocorticoids (such as 0.1% triamcinolone in Orabase) or choline salicylate (8.7%) gel. Symptomatic relief is achieved using local anaesthetic (0.1% triamcinolone in Orabase) or choline salicylate (8.7%) gel. Oral glucocorticoids may need to be considered (Box 21.25). Biopsy is occasionally necessary for diagnosis.

Rarely, patients with very severe, recurrent aphthous ulcers may need oral glucocorticoids.

Oral cancer may present in many ways (Box 21.26) and a high index of suspicion is required. All possible sources of local trauma or infection should be treated in patients with suspicious lesions and they should be reviewed after 2 weeks, with biopsy if the lesion persists. Small cancers can be resected but extensive surgery, with neck dissection to remove involved lymph nodes, may be necessary. Some patients can be treated with radical radiotherapy alone, and sometimes radiotherapy is also given after surgery to treat microscopic residual disease. Some tumours may be amenable to photodynamic therapy (PDT), avoiding the need for surgery.

Candidiasis

The yeast Candida albicans is a normal mouth commensal but it may proliferate to cause thrush. This occurs in babies, debilitated patients, people receiving glucocorticoid or antibiotic therapy, individuals with diabetes and immunosuppressed patients, especially those receiving cytotoxic therapy and those with HIV infection. White patches are seen on the tongue and buccal mucosa. Odynophagia or dysphagia suggests pharyngeal and oesophageal candidiasis. A clinical diagnosis is sufficient to instigate therapy, although brushings or biopsies can be obtained for mycological examination. Oral thrush is treated using nystatin or amphotericin suspensions or lozenges. Resistant cases or immunosuppressed patients may require oral fluconazole.

Parotitis

Parotitis is caused by viral or bacterial infection. Mumps causes a self-limiting acute parotitis (p. 240). Bacterial parotitis usually occurs as a complication of major surgery. It is a consequence of dehydration and poor oral hygiene, and can be avoided by good post-operative care. Patients present with painful parotid swelling and this can be complicated by abscess formation. Broad-spectrum antibiotics are required, while surgical drainage is necessary for abscesses. Other causes of salivary gland enlargement are listed in Box 21.27.
Gastro-oesophageal reflux disease

Gastro-oesophageal reflux resulting in heartburn affects approximately 30% of the general population.

Pathophysiology

Occasional episodes of gastro-oesophageal reflux are common in healthy individuals. Reflux is normally followed by oesophageal peristaltic waves that efficiently clear the gullet, alkaline saliva neutralises residual acid and symptoms do not occur. Gastro-oesophageal reflux disease develops when the oesophageal mucosa is exposed to gastroduodenal contents for prolonged periods of time, resulting in symptoms and, in a proportion of cases, oesophagitis. Several factors are known to be involved in the development of gastro-oesophageal reflux disease and these are shown in Figure 21.26.

Abnormalities of the lower oesophageal sphincter

The lower oesophageal sphincter is tonically contracted under normal circumstances, relaxing only during swallowing (p. 766).

Some patients with gastro-oesophageal reflux disease have reduced lower oesophageal sphincter tone, permitting reflux when intra-abdominal pressure rises. In others, basal sphincter tone is normal but reflux occurs in response to frequent episodes of inappropriate sphincter relaxation.

Hiatus hernia

Hiatus hernia (Box 21.29 and Fig. 21.27) causes reflux because the pressure gradient is lost between the abdominal and thoracic cavities, which normally pinches the hiatus. In addition, the oblique angle between the cardia and oesophagus disappears. Many patients who have large hiatus hernias develop reflux symptoms but the relationship between the presence of a hernia and symptoms is poor. Hiatus hernia is very common in individuals who have no symptoms, and some symptomatic patients have only a very small or no hernia. Nevertheless, almost all patients who develop oesophagitis, Barrett’s oesophagus or peptic strictures have a hiatus hernia.

Delayed oesophageal clearance

Defective oesophageal peristaltic activity is commonly found in patients who have oesophagitis. It is a primary abnormality, since it persists after oesophagitis has been healed by acid-suppressing drug therapy. Poor oesophageal clearance leads to increased acid exposure time.
The molecular events underlying progression of Barrett’s oesophagus to dysplasia and cancer are incompletely understood but inactivation of the tumour suppression protein p16 by loss of heterozygosity or promoter hypermethylation is a key event, followed by somatic inactivation of TP53, which promotes aneuploidy and tumour progression. Studies are in progress to develop biomarkers that will allow detection of those at higher cancer risk.

**Diagnosis**

This requires multiple systematic biopsies to maximise the chance of detecting intestinal metaplasia and/or dysplasia.

**Management**

Neither potent acid suppression nor anti-reflux surgery stops progression or induces regression of Barrett’s...
oesophagus, and treatment is indicated only for symptoms of reflux or complications, such as stricture. Endoscopic therapies, such as radiofrequency ablation or photodynamic therapy, can induce regression but at present are used only for those with dysplasia or intramucosal cancer. Regular endoscopic surveillance can detect dysplasia at an early stage and may improve survival but, because most Barrett’s oesophagus is undetected until cancer develops, surveillance strategies are unlikely to influence the overall mortality rate of oesophageal cancer. Surveillance is expensive and cost-effectiveness studies have been conflicting. It is currently recommended that patients with Barrett’s oesophagus with intestinal metaplasia, but without dysplasia, should undergo endoscopy at 3–5-yearly intervals if the length of the Barrettic segment is less than 3 cm and at 2–3-yearly intervals if the length is greater than 3 cm. Those with low-grade dysplasia should be endoscoped at 6-monthly intervals.

For those with high-grade dysplasia or intramucosal carcinoma, the treatment options are either oesophagectomy or endoscopic therapy, with a combination of endoscopic resection of any visibly abnormal areas and radiofrequency ablation of the remaining Barrett’s mucosa, as an ‘organ-preserving’ alternative to surgery. These cases should be discussed in a multidisciplinary team meeting and managed in specialist centres.

Anaemia

Iron deficiency anaemia can occur as a consequence of occult blood loss from long-standing oesophagitis. Most patients have a large hiatus hernia and bleeding can stem from subtle erosions in the neck of the sac (‘Cameron lesions’). Nevertheless, hiatus hernia is very common and other causes of blood loss, particularly colorectal cancer, must be considered in anaemic patients, even when endoscopy reveals oesophagitis.

Benign oesophageal stricture

Fibrous strictures can develop as a consequence of long-standing oesophagitis, especially in the elderly and those with poor oesophageal peristaltic activity. The typical presentation is with dysphagia that is worse for solids than for liquids. Bolus obstruction following ingestion of meat causes absolute dysphagia. A history of heartburn is common but not invariable; many elderly patients presenting with strictures have no preceding heartburn.

Diagnosis is by endoscopy, when biopsies of the stricture can be taken to exclude malignancy. Endoscopic balloon dilatation or bouginage is helpful. Subsequently, long-term therapy with a PPI drug at full dose should be started to reduce the risk of recurrent oesophagitis and stricture formation. The patient should be advised to chew food thoroughly and it is important to ensure adequate dentition.

Gastric volvulus

Occasionally, a massive intrathoracic hiatus hernia may twist on itself, leading to a gastric volvulus. This gives rise to complete oesophageal or gastric obstruction and the patient presents with severe chest pain, vomiting and dysphagia. The diagnosis is made by chest X-ray (air bubble in the chest) and barium swallow (see Fig. 21.27B). Most cases spontaneously resolve but recurrence is common, and surgery is usually advised after the acute episode has been treated by nasogastric decompression.

Investigations

Young patients who present with typical symptoms of gastro-oesophageal reflux, without worrying features such as dysphagia, weight loss or anaemia, can be treated empirically without investigation. Investigation is advisable if patients present over the age of 50–55 years, if symptoms are atypical or if a complication is suspected. Endoscopy is the investigation of choice. This is performed to exclude other upper gastrointestinal diseases that can mimic gastro-oesophageal reflux and to identify complications. A normal endoscopy in a patient with compatible symptoms should not preclude treatment for gastro-oesophageal reflux disease.

Twenty-four-hour pH monitoring is indicated if the diagnosis is unclear or surgical intervention is under consideration. This involves tethering a slim catheter with a terminal radiotelemetry pH-sensitive probe above the gastro-oesophageal junction. The intraluminal pH is recorded while the patient undergoes normal activities, and episodes of symptoms are noted and related to pH. A pH of less than 4 for more than 6–7% of the study time is diagnostic of reflux disease. In a few patients with difficult reflux, impedance testing can detect weakly acidic or alkaline reflux that is not revealed by standard pH testing.

Management

A treatment algorithm for gastro-oesophageal reflux is outlined in Figure 21.30. Lifestyle advice should be given, including weight loss, avoidance of dietary items that the patient finds worsen symptoms, elevation of the bed head in those who experience nocturnal symptoms, avoidance of late meals and cessation of smoking. Patients who fail to respond to these measures should be offered PPIs, which are usually effective in resolving symptoms and healing oesophagitis. Recurrence of symptoms is common when therapy is stopped and some patients require life-long treatment at the lowest acceptable dose. When dysmotility features are prominent, domperidone can be helpful. There is no evidence that H. pylori eradication has any therapeutic value. Proprietary antacids and alginates can also provide symptomatic benefit. H₂-receptor antagonist drugs relieve symptoms without healing oesophagitis.

Long-term PPI therapy is associated with reduced absorption of iron, B₁₂ and magnesium, and a small but increased risk of osteoporosis and fractures (odds ratio 1.2–1.5). The drugs also predispose to enteric infections with Salmonella, Campylobacter and possibly Clostridium difficile, and have recently been shown to have an undesirable impact on the composition of the gut.
microbiota. Long-term therapy increases the risk of Helicobacter-associated progression of gastric mucosal atrophy (see below) and \textit{H. pylori} eradication is advised in patients requiring PPIs for more than 1 year.

Patients who fail to respond to medical therapy, those who are unwilling to take long-term PPIs and those whose major symptom is severe regurgitation should be considered for laparoscopic anti-reflux surgery (see below) and by extensive erosive oesophagitis (p. 147). This may be complicated by oesophageal perforation with mediastinitis and by stricture formation. At the time of presentation, treatment is conservative, based on analgesia and nutritional support; vomiting and endoscopy should be avoided because of the high risk of oesophageal perforation. After the acute phase, a barium swallow should be performed to demonstrate the extent of stricture formation. Endoscopic dilatation is usually necessary but it is difficult and hazardous because strictures are often long, tortuous and easily perforated.

### Drugs

Potassium supplements and NSAIDs may cause oesophageal ulcers when the tablets are trapped above an oesophageal stricture. Liquid preparations of these drugs should be used in such patients. Bisphosphonates cause oesophageal ulceration and should be used with caution in patients with known oesophageal disorders.

### Eosinophilic oesophagitis

This is more common in children but increasingly recognised in young adults. It occurs more often in atopic individuals and is characterised by eosinophilic infiltration of the oesophageal mucosa. Patients present with dysphagia or food bolus obstruction more often than heartburn, and other symptoms, such as chest pain and vomiting, may be present. Endoscopy is usually normal but mucosal rings (that sometimes need endoscopic dilatation), strictures or a narrow-calibre oesophagus can occur. Children may respond to elimination diets but these are less successful in adults, who should first be treated with PPIs. The condition can be treated with 8–12 weeks of therapy with topical glucocorticoids, such as fluticasone or betamethasone. The usual approach is to prescribe a metered-dose inhaler but to tell the patient to spray this into the mouth and swallow it rather than inhale it. Refractory symptoms sometimes respond to montelukast, a leukotriene inhibitor.

### Motility disorders

#### Pharyngeal pouch

This occurs because of incoordination of swallowing within the pharynx, which leads to herniation through the criopharyngeus muscle and formation of a pouch. It is rare, affecting 1 in 100 000 people; it usually develops in middle life but can arise at any age. Many patients have no symptoms but regurgitation, hoarseness and dysphagia can be present. Some notice gurgling in the throat after swallowing. The investigation of choice is a barium swallow (see Fig. 21.12A), which demonstrates the pouch and reveals incoordination of swallowing, often with pulmonary aspiration. Endoscopy may be hazardous, since the instrument may enter and perforate the pouch. Surgical myotomy (‘diverticulotomy’), with or without resection of the pouch, is indicated in symptomatic patients.

#### Other causes of oesophagitis

### Infection

Oesophageal candidiasis occurs in debilitated patients and those taking broad-spectrum antibiotics or cytotoxic drugs. It is a particular problem in patients with HIV/AIDS, who are also susceptible to a spectrum of other oesophageal infections (p. 316).

### Corrosives

Suicide attempt by ingestion of strong household bleach or battery acid is followed by painful burns of the mouth and pharynx and by extensive erosive oesophagitis (p. 147). This may be complicated by oesophageal perforation with mediastinitis and by stricture formation. At the time of presentation, treatment...
Diseases of the oesophagus

• 795

Invasive than endoscopic dilatation. Both pneumatic dilatation and myotomy may be complicated by gastro-oesophageal reflux, and this can lead to severe oesophagitis because oesophageal clearance is so poor. For this reason, Heller’s myotomy is accompanied by a partial fundoplication anti-reflux procedure. PPI therapy is often necessary after surgery.

Other oesophageal motility disorders

Diffuse oesophageal spasm presents in late middle age with episodic chest pain that may mimic angina but is sometimes accompanied by transient dysphagia. Some cases occur in response to gastro-oesophageal reflux. Treatment is based on the use of PPI drugs when gastro-oesophageal reflux is present. Oral or sublingual nitrates or nifedipine may relieve attacks of pain. The results of drug therapy are often disappointing, as are the alternatives: pneumatic dilatation and surgical myotomy. ‘Nutcracker’ oesophagus is a condition in which extremely forceful peristaltic activity leads to episodic chest pain and dysphagia. Treatment is with nitrates or nifedipine. Some patients present with oesophageal motility disorders that do not fit into a specific disease entity. The patients are usually elderly and present with dysphagia and chest pain. Manometric abnormalities, ranging from poor peristalsis to spasm, occur. Treatment is with dilation and/or vasodilators for chest pain.

Secondary causes of oesophageal dysmotility

In systemic sclerosis or CREST syndrome (p. 1037), the muscle of the oesophagus is replaced by fibrous tissue, which causes failure of peristalsis leading to heartburn and dysphagia. Oesophagitis is often severe and benign fibrous strictures occur. These patients require long-term therapy with PPIs. Dermatomyositis, rheumatoid arthritis and myasthenia gravis may also cause dysphagia.

Benign oesophageal stricture

Benign oesophageal stricture is usually a consequence of gastro-oesophageal reflux disease (Box 21.31) and occurs most often in elderly patients who have poor oesophageal clearance. Rings, caused by submucosal fibrosis, are found at the oesophago-gastric junction (‘Schatzki ring’) and cause intermittent
dysphagia, often starting in middle age. A post-cricoid web is a rare complication of iron deficiency anaemia (Paterson–Kelly or Plummer–Vinson syndrome), and may be complicated by the development of squamous carcinoma. Benign strictures can be treated by endoscopic dilatation, in which wire-guided bougies or balloons are used to disrupt the fibrous tissue of the stricture.

**Tumours of the oesophagus**

**Benign tumours**
The most common is a leiomyoma. This is usually asymptomatic but may cause bleeding or dysphagia.

**Carcinoma of the oesophagus**
Squamous oesophageal cancer (Box 21.32) is relatively rare in Caucasians (4:100,000) but is more common in Iran, parts of Africa and China (200:100,000). Squamous cancer can occur in any part of the oesophagus and almost all tumours in the upper oesophagus are squamous cancers. Adenocarcinomas typically arise in the lower third of the oesophagus from Barrett’s oesophagus or from the cardia of the stomach. The incidence is increasing and is now approximately 5:100,000 in the UK; this is possibly because of the high prevalence of gastro-oesophageal reflux and Barrett’s oesophagus in Western populations. Despite modern treatment, the overall 5-year survival of patients presenting with oesophageal cancer is only 13%.

**Clinical features**
Most patients have a history of progressive, painless dysphagia for solid foods. Others present acutely because of food bolus obstruction. In the late stages, weight loss is often extreme; chest pain or hoarseness suggests mediastinal invasion. Fistulation between the oesophagus and the trachea or bronchial tree leads to coughing after swallowing, pneumonia and pleural effusion. Physical signs may be absent but, even at initial presentation, cachexia, cervical lymphadenopathy or other evidence of metastatic spread is common.

**Investigations**
The investigation of choice is upper gastrointestinal endoscopy (Fig. 21.32) with biopsy. A barium swallow demonstrates the site and length of the stricture but adds little useful information. Once a diagnosis has been made, investigations should be performed to stage the tumour and define operability. Thoracic and abdominal CT, often combined with positron emission tomography (PET-CT), should be carried out to identify metastatic spread and local invasion (Fig. 21.33). Invasion of the aorta, major airways or celiac axis usually precludes surgery, but patients with resectable disease on imaging should undergo EUS to determine the depth of penetration of the tumour into the oesophageal wall and to detect locoregional lymph node...
involvement (Fig. 21.34). These investigations will define the TNM stage of the disease (p. 1322).

**Management**

The treatment of choice is surgery if the patient presents at a point at which resection is possible. For very early superficial tumours, endoscopic submucosal dissection may offer an alternative to surgery but is not widely used outside of Japan and Korea. Patients with tumours that have extended beyond the wall of the oesophagus (T3) or that have lymph node involvement (N1) carry a 5-year survival of around 10%. This figure improves significantly, however, if the tumour is confined to the oesophageal wall and there is no spread to lymph nodes. Overall survival following ‘potentially curative’ surgery (all macroscopic tumour removed) is about 30% at 5 years but recent studies have suggested that this can be improved by neoadjuvant chemotherapy. Although squamous carcinomas are radiosensitive, radiotherapy alone is associated with a 5-year survival of only 5% but combined chemoradiotherapy for these tumours can achieve 5-year survival rates of 25–30%.

Approximately 70% of patients have extensive disease at presentation; in these, treatment is palliative and should focus on relief of dysphagia and pain. Endoscopic laser therapy or self-expanding metallic stents can be used to improve swallowing. Palliative radiotherapy may induce shrinkage of both squamous cancers and adenocarcinomas but symptomatic response may be slow. Quality of life can be improved by nutritional support and appropriate analgesia.

**Perforation of the oesophagus**

The most common cause is endoscopic perforation complicating dilatation or intubation. Malignant, corrosive or post-radiotherapy strictures are more likely to be perforated than peptic strictures. A perforated peptic stricture is managed conservatively using broad-spectrum antibiotics and parenteral nutrition; most cases heal within days. Malignant, caustic and radiotherapy stricture perforations require resection or stenting.

Spontaneous oesophageal perforation (‘Boerhaave’s syndrome’) results from forceful vomiting and retching. Severe chest pain and shock occur as oesophago-gastric contents enter the mediastinum and thoracic cavity. Subcutaneous emphysema, pleural effusions and pneumothorax develop. The diagnosis can be made using a water-soluble contrast swallow but, in difficult cases, both CT and careful endoscopy (usually in an intubated patient) may be required. Treatment is surgical. Delay in diagnosis is a key factor in the high mortality associated with this condition.

**Diseases of the stomach and duodenum**

### Gastritis

Gastritis is a histological diagnosis, although it can also be recognised at endoscopy.

#### Acute gastritis

Acute gastritis is often erosive and haemorrhagic. Neutrophils are the predominant inflammatory cell in the superficial epithelium. Many cases result from alcohol, aspirin or NSAID ingestion (Box 21.33). Acute gastritis often produces no symptoms but may cause dyspepsia, anorexia, nausea or vomiting, and haematemesis or melena. Many cases resolve quickly and do not merit investigation; in others, endoscopy and biopsy may be necessary to exclude peptic ulcer or cancer. Treatment should be directed at the underlying cause. Short-term symptomatic therapy with antacids, and acid suppression using PPIs, prokinetics (domperidone) or antiemetics (metoclopramide) may be necessary.

#### Chronic gastritis due to *Helicobacter pylori* infection

This is the most common cause of chronic gastritis (Box 21.33). The predominant inflammatory cells are lymphocytes and plasma cells. Correlation between symptoms and endoscopic or pathological findings is poor. Most patients are asymptomatic and do not require treatment but patients with dyspepsia may benefit from *H. pylori* eradication.

#### Autoimmune chronic gastritis

This involves the body of the stomach but spares the antrum; it results from autoimmune damage to parietal cells. The histological features are diffuse chronic inflammation, atrophy and loss of fundic glands, intestinal metaplasia and sometimes hyperplasia of enterochromaffin-like (ECL) cells. Circulating antibodies to parietal cell and intrinsic factor may be present. In some patients, the degree of gastric atrophy is severe and loss of intrinsic factor secretion leads to pernicious anaemia (p. 944). The gastritis itself is usually asymptomatic. Some patients have evidence of other organ-specific autoimmunity, particularly thyroid disease. In the long term, there is a two- to threefold increase in the risk of gastric cancer (see also p. 803).

#### Ménétrier’s disease

In this rare condition, the gastric pits are elongated and tortuous, with replacement of the parietal and chief cells by mucus-secreting cells. The cause is unknown but there is excessive production of transforming growth factor alpha (TGF-α). As a result, the...
mucosal folds of the body and fundus are greatly enlarged. Most patients are hypochlorhydric. While some patients have upper gastrointestinal symptoms, the majority present in middle or old age with protein-losing enteropathy (p. 811) due to exudation from the gastric mucosa. Endoscopy shows enlarged, nodular and coarse folds, although biopsies may not be deep enough to show all the histological features. Treatment with antisecretory drugs, such as PPIs with or without octreotide, may reduce protein loss and *H. pylori* eradication may be effective, but unresponsive patients require partial gastrectomy.

### Peptic ulcer disease

The term ‘peptic ulcer’ refers to an ulcer in the lower oesophagus, stomach or duodenum, in the jejunum after surgical anastomosis to the stomach or, rarely, in the ileum adjacent to a Meckel’s diverticulum. Ulcers in the stomach or duodenum may be acute or chronic; both penetrate the muscularis mucosae but the acute ulcer shows no evidence of fibrosis. Erosions do not penetrate the muscularis mucosae.

#### Gastric and duodenal ulcer

The prevalence of peptic ulcer (0.1–0.2%) is decreasing in many Western communities as a result of widespread use of *Helicobacter pylori* eradication therapy but it remains high in developing countries. The male-to-female ratio for duodenal ulcer varies from 5:1 to 2:1, while that for gastric ulcer is 2:1 or less. Chronic gastric ulcer is usually single; 90% are situated on the lesser curve within the antrum or at the junction between body and antral mucosa. Chronic duodenal ulcer usually occurs in the first part of the duodenum and 50% are on the anterior wall. Gastric and duodenal ulcers coexist in 10% of patients and more than one peptic ulcer is found in 10–15% of patients.

#### Pathophysiology

**H. pylori**

Peptic ulceration is strongly associated with *H. pylori* infection. The prevalence of the infection in developed nations rises with age and in the UK approximately 50% of people over the age of 50 years are infected. In the developing world infection is more common, affecting up to 90% of adults. These infections are probably acquired in childhood by person-to-person contact. The vast majority of colonised people remain healthy and asymptomatic, and only a minority develop clinical disease. Around 90% of duodenal ulcer patients and 70% of gastric ulcer patients are infected with *H. pylori*. The remaining 30% of gastric ulcers are caused by NSAIDs and this proportion is increasing in Western countries as a result of *H. pylori* eradication strategies.

*H. pylori* is Gram-negative and spiral, and has multiple flagella at one end, which make it motile, allowing it to burrow and live beneath the mucus layer adherent to the epithelial surface. It uses an adhesin molecule (BabA) to bind to the Lewis b antigen on epithelial cells. Here the surface pH is close to neutral and any acidity is buffered by the organism’s production of the enzyme urease. This produces ammonia from urea and raises the pH around the bacterium and between its two cell membrane layers. *H. pylori* exclusively colonises gastric-type epithelium and is found in the duodenum only in association with patches of gastric metaplasia. It causes chronic gastritis by provoking a local inflammatory response in the underlying epithelium (Fig. 21.35). This depends on numerous factors, notably expression of bacterial cagA and vacA genes. The CagA gene product is injected into epithelial cells, interacting with numerous cell-signalling pathways involved in cell replication and apoptosis. *H. pylori* strains expressing CagA (CagA+) are more often associated with disease than CagA– strains. Most strains also secrete a large pore-forming protein called VacA, which causes increased cell permeability, efflux of micronutrients from the epithelium, induction of apoptosis and suppression of local immune cell activity. Several forms of VacA exist and pathology is most strongly associated with the s1/ml form of the toxin.

The distribution and severity of *H. pylori*–induced gastritis determine the clinical outcome. In most people, *H. pylori* causes a mild pangastritis with little effect on acid secretion and the majority develop no significant clinical outcomes. In a minority (up
to 10% in the West), the infection causes an antral-predominant pattern of gastritis characterised by hypergastrinaemia and a very exaggerated acid production by parietal cells, which could lead to duodenal ulceration (Fig. 21.36). In a much smaller number of infected people, \( \text{H. pylori} \) causes a corpus-predominant pattern of gastritis leading to gastric atrophy and hypochlorhydria. This phenotype is much more common in Asian countries, particularly Japan, China and Korea. The hypochlorhydria allows other bacteria to proliferate within the stomach; these other bacteria continue to drive the chronic inflammation and produce mutagenic nitrates from dietary nitrates, predisposing to the development of gastric cancer (Fig. 21.37). The effects of \( \text{H. pylori} \) are more complex in gastric ulcer patients compared to those with duodenal ulcers. The ulcer probably arises because of impaired mucosal defence resulting from a combination of \( \text{H. pylori} \) infection, NSAIDs and smoking, rather than excess acid.

### NSAIDs

Treatment with NSAIDs is associated with peptic ulcers due to impairment of mucosal defences, as discussed on page 1002.

### Smoking

Smoking confers an increased risk of gastric ulcer and, to a lesser extent, duodenal ulcer. Once the ulcer has formed, it is more likely to cause complications and less likely to heal if the patient continues to smoke.

### Clinical features

Peptic ulcer disease is a chronic condition with spontaneous relapses and remissions lasting for decades, if not for life. The most common presentation is with recurrent abdominal pain that has three notable characteristics: localisation to the epigastrium, relationship to food and episodic occurrence. Occasional vomiting occurs in about 40% of ulcer subjects; persistent daily vomiting suggests gastric outlet obstruction. In one-third, the history is less characteristic, especially in elderly people or those taking NSAIDs. In this situation, pain may be absent or so slight that it is experienced only as a vague sense of epigastric unease. Occasionally, the only symptoms are anorexia and nausea, or early satiety after meals. In some patients, the ulcer is completely ‘silent’, presenting for the first time with anaemia from chronic undetected blood loss, as abrupt haematemesis or as acute perforation; in others, there is recurrent acute bleeding without ulcer pain. The diagnostic value of individual symptoms for peptic ulcer disease is poor; the history is therefore a poor predictor of the presence of an ulcer.

### Investigations

Endoscopy is the preferred investigation (Fig. 21.38). Gastric ulcers may occasionally be malignant and therefore must always be biopsied and followed up to ensure healing. Patients should be tested for \( \text{H. pylori} \) infection. The current options available are listed in Box 21.34. Some are invasive and require endoscopy; others are non-invasive. They vary in sensitivity and specificity. Breath tests or faecal antigen tests are best because of accuracy, simplicity and non-invasiveness.
Management

The aims of management are to relieve symptoms, induce healing and prevent recurrence. *H. pylori* eradication is the cornerstone of therapy for peptic ulcers, as this will successfully prevent relapse and eliminate the need for long-term therapy in the majority of patients.

### H. pylori eradication

All patients with proven ulcers who are *H. pylori*-positive should be offered eradication as primary therapy. Treatment is based on a PPI taken simultaneously with two antibiotics (from amoxicillin, clarithromycin and metronidazole) for at least 7 days. High-dose, twice-daily PPI therapy increases efficacy of treatment, as does extending treatment to 10–14 days. Success is achieved in 80–90% of patients, although adherence, side-effects (Box 21.35) and antibiotic resistance influence this. Resistance to amoxicillin is rare but rates of metronidazole resistance reach more than 50% in some countries and rates of clarithromycin resistance of 20–40% have recently become common. Where the latter exceed 15%, a quadruple therapy regimen, consisting of omeprazole (or another PPI), bismuth subcitrate, metronidazole and tetracycline (OBMT) for 10–14 days, is recommended. In areas of low clarithromycin resistance, this regimen should also be offered as second-line therapy to those who remain infected after initial therapy, once adherence has been checked. For those who are still colonised after two treatments, the choice lies between a third attempt guided by antimicrobial sensitivity testing, rescue therapy (levofloxacin, PPI and clarithromycin) or long-term acid suppression.

*H. pylori* and NSAIDs are independent risk factors for ulcer disease and patients requiring long-term NSAID therapy should first undergo eradication therapy to reduce ulcer risk. Subsequent co-prescription of a PPI along with the NSAID is advised but is not always necessary for patients being given low-dose aspirin, in whom the risk of ulcer complications is lower.

Other indications for *H. pylori* eradication are shown in Box 21.36. Eradication of the infection has proven benefits in several extragastric disorders, including unexplained vitamin B12 deficiency and iron deficiency anaemia, once sources of gastrointestinal bleeding have been looked for and excluded. Platelet counts improve and may normalise after eradication therapy in patients with idiopathic thrombocytopenic purpura (p. 979); the mechanism for this is unclear.

### General measures

Cigarette smoking, aspirin and NSAIDs should be avoided. Alcohol in moderation is not harmful and no special dietary advice is required.

### Maintenance treatment

Continuous maintenance treatment should not be necessary after successful *H. pylori* eradication. For the minority who do require it, the lowest effective dose of PPI should be used.

### Surgical treatment

Surgery is now rarely required for peptic ulcer disease but it is needed in some cases (Box 21.37). The operation of choice for a chronic non-healing gastric ulcer is partial gastrectomy, preferably with a Billroth I anastomosis, in which the ulcer itself and the ulcer-bearing area of the stomach are resected. The reason for this is to exclude an underlying
cancer. In an emergency, ‘under-running’ the ulcer for bleeding or ‘oversewing’ (patch repair) for perforation is all that is required, in addition to taking a biopsy. For giant duodenal ulcers, partial gastrectomy using a ‘Polya’ or Billroth II reconstruction may be required.

Complications of gastric resection or vagotomy

Up to 50% of patients who undergo gastric surgery for peptic ulcer surgery experience long-term adverse effects. In most cases these are minor but in 10% they significantly impair quality of life.

**Dumping** Rapid gastric emptying leads to distension of the proximal small intestine as the hypertonic contents draw fluid into the lumen. This leads to abdominal discomfort and diarrhoea after eating. Autonomic reflexes release a range of gastrointestinal hormones that provoke vasomotor features, such as flushing, palpitations, sweating, tachycardia and hypotension. Patients should therefore avoid large meals with high carbohydrate content.

**Chemical (bile reflux) gastropathy** Duodenogastric bile reflux leads to chronic gastropathy. Treatment with aluminium-containing antacids or sucrafate may be effective. A few patients require revisional surgery with creation of a Roux en Y loop to prevent bile reflux.

**Diarhoea and maldigestion** Diarhoea may develop after any peptic ulcer operation and usually occurs 1–2 hours after eating. Poor mixing of food in the stomach, with rapid emptying, inadequate mixing with pancreaticobiliary secretions, rapid transit and bacterial overgrowth, may lead to malabsorption. Diarhoea often responds to small, dry meals with a reduced intake of refined carbohydrates. Antidiarhoeal drugs, such as codeine phosphate (15–30 mg 4–6 times daily) or loperamide (2 mg after each loose stool), are helpful.

**Weight loss** Most patients lose weight shortly after surgery and 30–40% are unable to regain all the weight that is lost. The usual cause is reduced intake because of a small gastric remnant but diarhoea and mild steatorrhoea also contribute.

**Anaemia** Anaemia is common many years after subtotal gastrectomy. Iron deficiency is the most common cause; folic acid and B12 deficiency are much less frequent. Inadequate dietary intake of iron and folate, lack of acid and intrinsic factor secretion, mild chronic low-grade blood loss from the gastric remnant and recurrent ulceration are responsible.

**Metabolic bone disease** Both osteoporosis and osteomalacia can occur as a consequence of calcium and vitamin D malabsorption.

**Gastric cancer** An increased risk of gastric cancer has been reported from several epidemiological studies. Surgery itself is an independent risk factor for late development of malignancy in the gastric remnant but the risk is higher in those with hypochlorhydria, duodenogastric reflux of bile, smoking and H. pylori infection. Although the relative risk is increased, the absolute risk of cancer remains low and endoscopic surveillance is not indicated following gastric surgery.

**Complications of peptic ulcer disease**

**Perforation**

When perforation occurs, the contents of the stomach escape into the peritoneal cavity, leading to peritonitis. This is more common in duodenal than in gastric ulcers and is usually found with ulcers on the anterior wall. About one-quarter of all perforations occur in acute ulcers and NSAIDs are often incriminated. Perforation can be the first sign of ulcer and a history of recurrent epigastric pain is uncommon. The most striking symptom is sudden, severe pain; its distribution follows the spread of the gastric contents over the peritoneum. The pain initially develops in the upper abdomen and rapidly becomes generalised; shoulder tip pain is caused by irritation of the diaphragm. The pain is accompanied by shallow respiration, due to limitation of diaphragmatic movements, and by shock. The abdomen is held immobile and there is generalised ‘board-like’ rigidity. Bowel sounds are absent and liver dullness to percussion decreases due to the presence of gas under the diaphragm. After some hours, symptoms may improve, although abdominal rigidity remains. Later, the patient’s condition deteriorates as general peritonitis develops. In at least 50% of cases, an erect chest X-ray shows free air beneath the diaphragm (see Fig. 21.11B, p. 773). If not, a water-soluble contrast swallow will confirm leakage of gastroduodenal contents. After resuscitation, the acute perforation should be treated surgically, either by simple closure or by conversion of the perforation into a pyloroplasty if it is large. On rare occasions, a ‘Polya’ partial gastrectomy is required. Following surgery, H. pylori should be treated (if present) and NSAIDs avoided. Perforation carries a mortality of 25%, reflecting the advanced age and significant comorbidity of the population that are affected.

**Gastric outlet obstruction**

The causes are shown in Box 21.39. The most common is an ulcer in the region of the pylorus. The presentation is with nausea, vomiting and abdominal distension. Large quantities of gastric content are often vomited and food eaten 24 hours or more previously may be recognised. Physical examination may show evidence of wasting and dehydration. A succession splash may be elicited 4 hours or more after the last meal or drink. Visible gastric peristalsis is diagnostic of gastric outlet obstruction. Loss of acidic gastric contents leads to alkalosis and dehydration with low serum chloride and potassium and raised serum bicarbonate and urea concentrations (hypochloraemic metabolic alkalosis).

### 21.38 Peptic ulcer disease in old age

- **Gastroduodenal ulcers**: have a greater incidence, admission rate and mortality.
- **Causes**: high prevalence of *H. pylori*, use of non-steroidal anti-inflammatory drugs and impaired defence mechanisms.
- **Atypical presentations**: pain and dyspepsia are frequently absent or atypical. Older people often develop complications, such as bleeding or perforation, without a dyspeptic history.
- **Bleeding**: older patients require more intensive management because they have more limited reserve to withstand hypovolaemia.

### 21.39 Differential diagnosis and management of gastric outlet obstruction

Paradoxical aciduria occurs because of enhanced renal absorption of Na⁺ in exchange for H⁺. Endoscopy should be performed after the stomach has been emptied using a wide-bore nasogastric tube. Intravenous correction of dehydration is undertaken and, in severe cases, at least 4 L of isotonic saline and 80 mmol of potassium may be necessary during the first 24 hours. In some patients, PPI drugs heal ulcers, relieve pyloric oedema and overcome the need for surgery. Endoscopic balloon dilatation of benign stenoses may be possible in some patients but in others partial gastrectomy is necessary; this is best done after a 7-day period of nasogastric aspiration, which enables the stomach to return to normal size. A gastroenterostomy is an alternative operation but, unless this is accompanied by vagotomy, patients will require long-term PPI therapy to prevent stomal ulceration.

Bleeding
See page 780.

Zollinger–Ellison syndrome
This is a rare disorder characterised by the triad of severe peptic ulceration, gastric acid hypersecretion and a neuro-endocrine tumour (p. 678) of the pancreas or duodenum (‘gastrinoma’). It probably accounts for about 0.1% of all cases of duodenal ulceration. The syndrome occurs in either sex at any age, although it is most common between 30 and 50 years of age.

Pathophysiology
The tumour secretes gastrin, which stimulates acid secretion to its maximal capacity and increases the parietal cell mass three- to sixfold. The acid output may be so great that it reaches the upper small intestine, reducing the luminal pH to 2 or less. Pancreatic lipase is inactivated and bile acids are precipitated. Diarrhoea and steatorrhoea result. Around 90% of tumours occur in the pancreatic head or proximal duodenal wall. At least half are multiple and tumour size can vary from 1 mm to 20 cm. Approximately one-half to two-thirds are malignant but are often slow-growing. Between 20% and 60% of patients have multiple endocrine neoplasia (MEN) type 1 (p. 688).

Clinical features
The presentation is with severe and often multiple peptic ulcers in unusual sites, such as the post-bulbar duodenum, jejunum or oesophagus. There is a poor response to standard ulcer therapy. The history is usually short, and bleeding and perforations are common. Diarrhoea is seen in one-third or more of patients and can be the presenting feature.

Investigations
Hypersecretion of acid under basal conditions, with little increase following pentagastrin, may be confirmed by gastric aspiration. Serum gastrin levels are grossly elevated (10- to 1000-fold). Injection of the hormone secretin normally causes no change to its maximal capacity and increases the parietal cell mass three- to sixfold. The acid output may be so great that it reaches the upper small intestine, reducing the luminal pH to 2 or less. Pancreatic lipase is inactivated and bile acids are precipitated. Diarrhoea and steatorrhoea result. Around 90% of tumours occur in the pancreatic head or proximal duodenal wall. At least half are multiple and tumour size can vary from 1 mm to 20 cm. Approximately one-half to two-thirds are malignant but are often slow-growing. Between 20% and 60% of patients have multiple endocrine neoplasia (MEN) type 1 (p. 688).

Management
Some 30% of small and single tumours can be localised and resected but many tumours are multifocal (especially in the context of MEN 1). Some patients present with metastatic disease and, in these circumstances, surgery is inappropriate. In the majority of these individuals, continuous therapy with omeprazole or other PPIs can be successful in healing ulcers and alleviating diarrhoea, although double the normal dose is required. The synthetic somatostatin analogue, octreotide, given by subcutaneous injection, reduces gastrin secretion and may be of value. Other treatment options for pancreatic neuro-endocrine tumours are discussed on page 678. Overall 5-year survival is 60–75% and all patients should undergo genetic screening for MEN 1.

Functional disorders

Functional dyspepsia
This is defined as chronic dyspepsia in the absence of organic disease. Other commonly reported symptoms include early satiety, fullness, bloating and nausea. ‘Ulcer-like’ and ‘dysmotility-type’ subgroups are often reported but there is overlap between these and with irritable bowel syndrome.

Pathophysiology
The cause is poorly understood but probably covers a spectrum of mucosal, motility and psychiatric disorders.

Clinical features
Patients are usually young (<40 years) and women are affected twice as commonly as men. Abdominal discomfort is associated with a combination of other ‘dyspeptic’ symptoms, the most common being nausea, satiety and bloating after meals. Morning symptoms are characteristic and pain or nausea may occur on waking. Direct enquiry may elicit symptoms suggestive of irritable bowel syndrome. Peptic ulcer disease must be considered, while in older people intra-abdominal malignancy is a prime concern. There are no diagnostic signs, apart from inappropriate tenderness on abdominal palpation, perhaps. Symptoms may appear disproportionate to clinical well-being and there is no weight loss. Patients often appear anxious. A drug history should be taken and the possibility of a depressive illness should be considered. Pregnancy should be ruled out in young women before radiological studies are undertaken. Alcohol misuse should be suspected when early-morning nausea and retching are prominent.

Investigations
The history will often suggest the diagnosis. All patients should be checked for H. pylori infection and patients over the age of 55 years should undergo endoscopy to exclude mucosal disease. While an ultrasound scan may detect gallstones, these are rarely responsible for dyspeptic symptoms.

Management
The most important elements are explanation and reassurance. Possible psychological factors should be explored and the concept of psychological influences on gut function should be explained. Idiosyncratic and restrictive diets are of little benefit but smaller portions and fat restriction may help.

Up to 10% of patients benefit from H. pylori eradication therapy and this should be offered to infected individuals. Eradication also removes a major risk factor for peptic ulcers and gastric cancer but at the cost of a small risk of side-effects and worsening symptoms of underlying gastro-oesophageal reflux disease. Drug treatment is not especially successful but merits trial. Antacids,
such as hydrotalcite, are sometimes helpful. Prokinetic drugs, such as metoclopramide (10 mg 3 times daily) or domperidone (10–20 mg 3 times daily), may be given before meals if nausea, vomiting or bloating is prominent. Metoclopramide may induce extrapyramidal side-effects, including tardive dyskinesia in young patients. H2-receptor antagonist drugs may be tried if night pain or heartburn is troublesome. Low-dose tricyclic agents, such as amitriptyline, are of value in up to two-thirds. Symptoms that can be associated with an identifiable cause of stress resolve with appropriate counselling. Some patients have major psychological disorders that result in persistent or recurrent symptoms and need behavioural or other formal psychotherapy (p. 1190).

Functional causes of vomiting

Psychogenic retching or vomiting may arise in anxiety. It typically occurs on wakening or immediately after breakfast, and only rarely later in the day. The disorder is probably a reaction to facing up to the worries of everyday life; in the young, it can be due to school phobia. Early morning vomiting also occurs in pregnancy, alcohol misuse and depression. Although functional vomiting may occur regularly over long periods, there is little or no weight loss. Children, and less often adults, sometimes suffer from acute and recurrent disabling bouts of vomiting for days at a time. The cause of this cyclical vomiting syndrome is unknown but in some adults it is associated with cannabis use.

In all patients it is essential to exclude other common causes (p. 780). Tranquillisers and antiepileptic drugs (metoclopramide 10 mg 3 times daily, domperidone 10 mg 3 times daily, prochlorperazine 5–10 mg 3 times daily) have only a secondary place in management. Antidepressants in full dose may be effective (p. 1199).

Gastroparesis

Defective gastric emptying without mechanical obstruction of the stomach or duodenum can occur as a primary event, due to inherited or acquired disorders of the gastric pacemaker, or can be secondary to disorders of autonomic nerves (particularly diabetic neuropathy) or the gastroduodenal musculature (systemic sclerosis, myotonic dystrophies and amyloidosis). Drugs such as opiates, calcium channel antagonists and those with anticholinergic activity (tricyclics, phenothiazines) can also cause gastroparesis. Early satiety and recurrent vomiting are the major symptoms; abdominal fullness and a succussion splash may be present on examination. Treatment is based on small, frequent, low-fat meals and the use of metoclopramide and domperidone. In severe cases, nutritional failure can occur and long-term jejunostomy feeding or total parenteral nutrition is required. Surgical insertion of a gastric neurostimulator has been successful in some cases, especially those complicating diabetic autonomic neuropathy.

Tumours of the stomach

Gastric carcinoma

Gastric carcinoma is the third leading cause of cancer death worldwide but there is marked geographical variation in incidence. It is most common in China, Japan, Korea (incidence 40/100 000 males), Eastern Europe and parts of South America (20/100 000). Rates in the UK are 12/100 000 for men. In most countries, the incidence is 50% lower in women. In both sexes, it rises sharply after 50 years of age. Studies of Japanese migrants to the USA have revealed a much lower incidence in the second generation, confirming the importance of environmental factors. The overall prognosis is poor, with less than 30% surviving 5 years, and the best hope for improved survival lies in more efficient detection of tumours at an earlier stage.

Pathophysiology

Infection with H. pylori plays a key pathogenic role and the infection has been classified by the International Agency for Research on Cancer (IARC) as a definite human carcinogen. It is associated with chronic atrophic gastritis, gastric mucosal atrophy and gastric cancer (Fig. 21.39). It has been estimated that H. pylori infection may contribute to the occurrence of gastric cancer in 70% of cases. Although the majority of H. pylori-infected individuals have normal or increased acid secretion, a few become hypo- or achlorhydric and these people are thought to be at greatest risk. H. pylori-induced chronic inflammation with generation of reactive oxygen species and depletion of the normally abundant antioxidant ascorbic acid are also important. There is strong evidence that H. pylori eradication, especially if achieved before irreversible pre-neoplastic changes (atrophy and intestinal metaplasia) have developed, reduces the risk of cancer development in high-risk populations and is cost-effective.

Diets rich in salted, smoked or pickled foods and the consumption of nitrates and nitrites may increase cancer risk. Carcinogenic N-nitroso-compounds are formed from nitrates by the action of nitrite-reducing bacteria that colonise the achlorhydric stomach. Diets lacking in fresh fruit and vegetables, as well as vitamins C and A, may also contribute. Other risk factors are listed in Box 21.40. No predominant genetic abnormality has been identified, although cancer risk is increased two- to threefold in first-degree relatives of patients, and links with blood group A have been reported. Some host genetic factors related to inflammatory genes and prostate stem cell antigen have recently been associated with increased risk of gastric cancer. Rarely, gastric cancer may be inherited in an autosomal dominant manner in association with mutations of the E-cadherin (CDH1) gene.
Virtually all tumours are adenocarcinomas arising from mucus-secreting cells in the base of the gastric crypts. Most develop on a background of chronic atrophic gastritis with intestinal metaplasia and dysplasia. Cancers are either ‘intestinal’, arising from areas of intestinal metaplasia with histological features reminiscent of intestinal epithelium, or ‘diffuse’, arising from normal gastric mucosa. Intestinal carcinomas are more common and arise against a background of chronic mucosal injury. Diffuse cancers tend to be poorly differentiated and occur in younger patients. In the developing world, 50% of gastric cancers develop in the antrum; 20–30% occur in the gastric body, often on the greater curve; and 20% are found in the cardia. In Western populations, however, proximal gastric tumours are becoming more common than those arising in the body and distal stomach. This change in disease pattern may be a reflection of changes in lifestyle or the decreasing prevalence of *H. pylori* infection. Diffuse submucosal infiltration by a scirrhous cancer (limis plastica) is uncommon. Early gastric cancer is defined as cancer confined to the mucosa or submucosa. It is more often recognised in Japan, where widespread screening is practised. Some cases can be cured by endoscopic mucosal or submucosal resection. The majority of patients (>80%) in the West, however, present with advanced gastric cancer.

**Clinical features**

Early gastric cancer is usually asymptomatic but may be discovered during endoscopy for investigation of dyspepsia. Two-thirds of patients with advanced cancers have weight loss and 50% have ulcer-like pain. Anorexia and nausea occur in one-third, while early satiety, haematemesis, melena and dyspepsia alone are less common. Dysphagia occurs in tumours of the gastric cardia that obstruct the gastro-oesophageal junction. Anaemia from occult bleeding is also common. Examination may reveal no abnormalities but signs of weight loss, anaemia and a palpable epigastric mass are not infrequent. Jaundice or ascites signifies metastatic spread. Occasionally, tumour spread occurs to the supraclavicular lymph nodes (Troisier’s sign), umbilicus (Sister Joseph’s nodule) or ovaries (Krukenberg tumour). Paraneoplastic phenomena, such as acanthosis nigricans, thrombophlebitis (Trousseau’s sign) and dermatomyositis, occur rarely. Metastases arise most commonly in the liver, lungs, peritoneum and bone marrow.

**Investigations**

Upper gastrointestinal endoscopy is the investigation of choice (Fig. 21.40) and should be performed promptly in any dyspeptic patient with ‘alarm features’ (see Box 21.15, p. 779). Multiple biopsies from the edge and base of a gastric ulcer are required. Barium meal is a poor alternative, since any abnormalities must be followed by endoscopy and biopsy. Once the diagnosis is made, further imaging is necessary for staging and assessment of resectability. CT will provide evidence of intra-abdominal spread or liver metastases. Even with these techniques, laparoscopy with peritoneal washings is required to determine whether the tumour is resectable, as it is the only modality that will reliably detect peritoneal spread.

**Management**

**Surgery**

Resection offers the only hope of cure and this can be achieved in about 90% of patients with early gastric cancer. For the majority of patients with locally advanced disease, total gastrectomy with lymphadenectomy is the operation of choice, preserving the spleen if possible. Proximal tumours involving the oesophago-gastric junction also require a distal oesophagectomy. Small, distally sited tumours can be managed by a partial gastrectomy with lymphadenectomy and either a Billroth I or a Roux en Y reconstruction. More extensive lymph node resection may increase survival rates but carries greater morbidity. Even for those who cannot be cured, palliative resection may be necessary when patients present with bleeding or gastric outlet obstruction. Following surgery, recurrence is much more likely if serosal penetration has occurred, although complete removal of all macroscopic tumour combined with lymphadenectomy will achieve a 50–60% 5-year survival. Perioperative chemotherapy with epirubicin, cisplatin and fluorouracil (ECF) improves survival rates.

**Palliative treatment**

In patients with inoperable tumours, survival can be improved and palliation of symptoms achieved with chemotherapy using 5-fluorouracil and cisplatin, ECF or other platinum- and taxane-based regimens. The biological agent trastuzumab may benefit some patients whose tumours over-express HER2 (p. 1322). Endoscopic laser ablation for control of dysphagia or recurrent bleeding benefits some patients. Carcinomas at the cardia or pylorus may require endoscopic dilatation or insertion of expandable metallic stents for relief of dysphagia or vomiting. A nasogastric tube may offer temporary relief of vomiting due to gastric outlet obstruction (Box 21.41).
on the stage at diagnosis. Features predicting a favourable prognosis are stage I or II disease, small resectable tumours, tumours with low-grade histology, and age below 60 years.

### Other tumours of the stomach

Gastrointestinal stromal cell tumours (GISTs), arising from the interstitial cells of Cajal, are occasionally found at upper gastrointestinal endoscopy. They are differentiated from other mesenchymal tumours by expression of the c-kit proto-oncogene, which encodes a tyrosine kinase receptor. These tumours, particularly the smaller lesions of less than 2 cm, are usually benign and asymptomatic, but the larger ones may have malignant potential and may occasionally be responsible for dyspepsia, ulceration and gastrointestinal bleeding. Small lesions (<2 cm) are usually followed by endoscopy, while larger ones require surgical resection. Very large lesions should be treated pre-operatively with imatinib (a tyrosine kinase inhibitor) to reduce their size and make surgery easier. Imatinib can also provide prolonged control of metastatic GISTs.

A variety of polyps occur. Hyperplastic polyps and fundic cystic gland polyps are common and of no consequence. Adenomatous polyps are rare but have malignant potential and should be removed endoscopically.

Occasionally, gastric carcinoid tumours are seen in the fundus and body in patients with long-standing pernicious anaemia. These benign tumours arise from ECL or other endocrine cells, and are often multiple but rarely invasive. Unlike carcinoid tumours arising elsewhere in the gastrointestinal tract, they usually run a benign and favourable course. Large (>2 cm) carcinoids may, however, metastasise and should be removed. Rarely, small nodules of ectopic pancreatic exocrine tissue are found. These ‘pancreatic rests’ may be mistaken for gastric neoplasms and usually cause no symptoms. EUS is the most useful investigation.

### Coeliac disease

Coeliac disease is an inflammatory disorder of the small bowel occurring in genetically susceptible individuals, which results from intolerance to wheat gluten and similar proteins found in rye, barley and, to a lesser extent, oats. It can result in malabsorption and responds to a gluten-free diet. The condition occurs worldwide but is more common in northern Europe. The prevalence in the UK is approximately 1%, although 50% of these people are asymptomatic. These include both undiagnosed ‘silent’ cases of the disease and cases of ‘latent’ coeliac disease – genetically susceptible people who may later develop clinical coeliac disease.

### Pathophysiology

The precise mechanism of mucosal damage is unclear but immunological responses to gluten play a key role (Fig. 21.41). There is a strong genetic component, with around 10% of first-degree relatives of an index case affected, and there is strong (approximately 75%) concordance in monozygotic twins. There is a strong association with human leukocyte antigen (HLA)-DQ2/DQ8. Dysbiosis of the intestinal microbiota has been identified but it is unclear if this is pathological or a response to the underlying mucosal changes.

### Gastric lymphoma

This is a rare tumour, accounting for less than 5% of all gastric malignancies. The stomach is, however, the most common site for extranodal non-Hodgkin lymphoma and 60% of all primary gastrointestinal lymphomas occur at this site. Lymphoid tissue is not found in the normal stomach but lymphoid aggregates develop in the presence of H. pylori infection. Indeed, H. pylori infection is closely associated with the development of a low-grade lymphoma (classified as extranodal marginal-zone lymphomas of MALT type). EUS plays an important role in staging these lesions by accurately defining the depth of invasion into the gastric wall. The clinical presentation is similar to that of gastric cancer and endoscopically the tumour appears as a polypoid or ulcerating mass. While initial treatment of low-grade lesions confined to the superficial layers of the gastric wall consists of H. pylori eradication and close observation, 25% contain t(11:18) chromosomal translocations. In these cases, additional radiotherapy or chemotherapy is usually necessary. High-grade B-cell lymphomas should be treated by a combination of rituximab, chemotherapy (p. 962), surgery and radiotherapy. The choice depends on the site and extent of tumour, the presence of comorbid illnesses, and other factors, such as symptoms of bleeding and gastric outflow obstruction. The prognosis depends on the stage at diagnosis. Features predicting a favourable
usually characteristic but other causes of villous atrophy should be considered (Box 21.43 and Fig. 21.42). Sometimes the villi appear normal but there are excess numbers of intra-epithelial lymphocytes (IELs). Lymphocytes infiltrate the lamina propria and an increase in intra-epithelial lymphocytes (IELs), crypt hyperplasia and villous atrophy ensue.

**Clinical features**
Coeliac disease can present at any age. In infancy, it occurs after weaning on to cereals and typically presents with diarrhoea, malabsorption and failure to thrive. In older children, it may present with non-specific features, such as delayed growth. Features of malnutrition are found on examination and mild abdominal distension may be present. Affected children have growth and pubertal delay, leading to short stature in adulthood.

In adults, the disease usually presents during the third or fourth decade and females are affected twice as often as males. The presentation is highly variable, depending on the severity and extent of small bowel involvement. Some have florid malabsorption, while others develop non-specific symptoms, such as tiredness, weight loss, folate deficiency or iron deficiency anaemia. Other presentations include oral ulceration, dyspepsia and bloating. Unrecognised coeliac disease is associated with mild under-nutrition and osteoporosis.

Coeliac disease is associated with other HLA-linked autoimmune disorders and with certain other diseases (Box 21.42). In some centres, people at higher risk of developing coeliac disease, such as those with type 1 diabetes, may undergo periodic antibody screening. Such screening may identify people with asymptomatic or minimally symptomatic disease; there is controversy about the optimum management strategy for such individuals.

**Investigations**
These are performed to confirm the diagnosis and to look for consequences of malabsorption.

**Duodenal biopsy**
Endoscopic small bowel biopsy is the gold standard. Endoscopic appearances should not preclude biopsy, as the mucosa usually looks normal. As the histological changes can be patchy, an adequate number of biopsies – currently, more than four biopsies from the second part of the duodenum plus one from the duodenal bulb – should be retrieved. The histological features are
anti-endomysial antibodies. If the antibody screen is positive, adult patients should remain on a gluten-containing diet until duodenal biopsies are taken. High-titre serology in children can be diagnostic without the need for endoscopy and biopsy. Antibody titres usually become negative with successful treatment.

Anti-endomysial antibodies of the IgA class are detectable by immunofluorescence in most untreated cases. They are sensitive (85–95%) and specific (approximately 99%) for the diagnosis, except in very young infants. IgG antibodies, however, must be analysed in patients with coexisting IgA deficiency. The tTG assay has become the serological test of choice in many countries, as it is easier to perform, is semi-quantitative, has more than 95% sensitivity and specificity, and is more accurate in patients with IgA deficiency.

Haematology and biochemistry
A full blood count may show microcytic or macrocytic anaemia from iron or folate deficiency and features of hyposplenism (target cells, spherocytes and Howell–Jolly bodies). Biochemical tests may reveal reduced concentrations of calcium, magnesium, total protein, albumin or vitamin D. Serum IgA measurement is required to ensure an appropriate IgA response and to allow analysis of serological testing.

Other investigations
Measurement of bone density should be considered to look for evidence of osteoporosis, especially in older patients and post-menopausal women.

Management
The aims are to correct existing deficiencies of micronutrients, such as iron, folate, calcium and/or vitamin D, and to achieve mucosal healing through a life-long gluten-free diet. This requires the exclusion of wheat, rye, barley and initially oats, although oats may be re-introduced safely in most patients after 6–12 months. Initially, frequent dietary counselling is required to make sure the diet is being observed, as the most common reason for failure to improve with dietary treatment is accidental or unrecognised gluten ingestion. Mineral and vitamin supplements are also given when indicated but are seldom necessary when a strict gluten-free diet is being observed, as the most common reason for failure to improve with dietary treatment is accidental or unrecognised gluten ingestion. Mineral and vitamin supplements are also given when indicated but are seldom necessary when a strict gluten-free diet is adhered to. Booklets produced by coeliac societies in many countries, containing diet sheets and recipes for the use of gluten-free flour, are of great value. Dietetic follow-up is key to management. Patients should be followed up after initiation of a gluten-free diet, with assessment of symptoms, weight and nutritional status, and blood should be taken for measurement of tTG or anti-endomysial antibodies. There are currently no additional non-invasive tests to assess small bowel mucosal healing. Repeat small bowel biopsies are not required routinely but should be considered in patients whose symptoms fail to improve and those in whom antibody levels remain high. In these circumstances, if the diet is satisfactory, then other conditions, such as pancreatic insufficiency or microscopic colitis, should be sought, as should complications of coeliac disease, such as ulcerative jejunitis or enteropathy-associated T-cell lymphoma. There remain a small number of patients who fail to respond adequately to a gluten-free diet and they require therapy with glucocorticoids or immunosuppressive drugs.

Complications
A twofold-increased risk of malignancy, particularly of enteropathy-associated T-cell lymphoma, small bowel carcinoma and squamous carcinoma of the oesophagus, has been reported.

A few patients develop ulcerative jejuno-ileitis. This may present with fever, pain, obstruction or perforation. This diagnosis can be made by barium studies or enteroscopy but laparotomy and full-thickness biopsy may be required. Treatment is difficult. Glucocorticoids are used with mixed success and some patients require surgical resection and parenteral nutrition. The course is often progressive.

Osteoporosis and osteomalacia may occur in patients with longstanding, poorly controlled coeliac disease. These complications are less common in those who adhere strictly to a gluten-free diet.

Dermatitis herpetiformis
This is characterised by crops of intensely itchy blisters over the elbows, knees, back and buttocks (p. 1256). Immunofluorescence shows granular or linear IgA deposition at the dermo-epidermal junction. Almost all patients have partial villous atrophy on duodenal biopsy, identical to that seen in coeliac disease, even though they usually have no gastrointestinal symptoms. In contrast, fewer than 10% of coeliac patients have evidence of dermatitis herpetiformis, although both disorders are associated with the same histocompatibility antigen groups. The rash usually responds to a gluten-free diet but some patients require additional treatment with dapsone (100–150 mg daily).

Tropical sprue
Tropical sprue is defined as chronic, progressive malabsorption in a patient in or from the tropics, associated with abnormalities of small intestinal structure and function. The disease occurs mainly in the West Indies and in southern India, Malaysia and Indonesia.

Pathophysiology
The epidemiological pattern and occasional epidemics suggest that an infective agent may be involved. Although no single bacterium has been isolated, the condition often begins after an acute diarrhoeal illness. Small bowel bacterial overgrowth with *Escherichia coli*, *Enterobacter* and *Klebsiella* is frequently seen. The changes closely resemble those of coeliac disease.
Clinical features
There is diarrhoea, abdominal distension, anorexia, fatigue and weight loss. In visitors to the tropics, the onset of severe diarrhoea may be sudden and accompanied by fever. When the disorder becomes chronic, the features of megaloblastic anaemia (vitamin B₁₂ and folic acid malabsorption) and other deficiencies, including ankle oedema, glossitis and stomatitis, are common. Remissions and relapses may occur. The differential diagnosis in the indigenous tropical population is an infective cause of diarrhoea. The important differential diagnosis in visitors to the tropics is giardiasis (p. 287).

Management
Tetracycline (250 mg 4 times daily for 28 days) is the treatment of choice and brings about long-term remission or cure. In most patients, pharmacological doses of folic acid (5 mg daily) improve symptoms and jejunal morphology. In some cases, treatment must be prolonged before improvement occurs and occasionally patients must leave the tropics.

Small bowel bacterial overgrowth (‘blind loop syndrome’)
The normal duodenum and jejunum contain fewer than 10⁴/mL organisms, which are usually derived from saliva. The count of coliform organisms never exceeds 10⁸/mL. In bacterial overgrowth, there may be 10⁸–10¹⁰/mL organisms, most of which are normally found only in the colon. Disorders that impair the normal physiological mechanisms controlling bacterial proliferation in the intestine predispose to bacterial overgrowth (Box 21.44). The most important are loss of gastric acidity, impaired intestinal motility and structural abnormalities that allow colonic bacteria to gain access to the small intestine or provide a secluded haven from the peristaltic stream.

Pathophysiology
Bacterial overgrowth can occur in patients with small bowel diverticuli. Another cause is diabetic autonomic neuropathy (p. 760), which reduces small bowel motility and affects enteroocyte secretion. In systemic sclerosis, bacterial overgrowth arises because the circular and longitudinal layers of the intestinal muscle are fibrosed and motility is abnormal. In idiopathic hypogammaglobulinaemia (p. 78), bacterial overgrowth occurs because the IgA and IgM levels in serum and jejunal secretions are reduced. Chronic diarrhoea and malabsorption occur because of bacterial overgrowth and recurrent gastrointestinal infections (particularly giardiasis, p. 287).

Clinical features
The patient presents with watery diarrhoea and/or steatorrhoea, and with anaemia due to B₁₂ deficiency. These arise because of deconjugation of bile acids, which impairs micelle formation, and because of bacterial utilisation of vitamin B₁₂. There may also be symptoms from the underlying intestinal cause.

Investigations
The diagnosis of blind loops or fistulae can often be made by barium small bowel meal and follow-through or small bowel MRI enterography. Endoscopic duodenal biopsies are useful in excluding coeliac disease. Jejunal contents for bacteriological examination can also be aspirated at endoscopy but laboratory analysis requires anaerobic and aerobic culture techniques. Bacterial overgrowth can also be diagnosed non-invasively using hydrogen breath tests, although they lack sensitivity. These simple, non-radioactive tests involve serial measurement of breath samples for hydrogen after oral ingestion of 50 g of glucose or lactulose. If bacteria are present within the small bowel, they rapidly metabolise the glucose, causing an early rise in exhaled hydrogen, in advance of that normally resulting from metabolism by colonic flora. Biochemical analysis may reveal low serum levels of vitamin B₁₂, with normal or elevated folate levels because the bacteria produce folic acid. Hypogammaglobulinaemia can be diagnosed by measurement of serum immunoglobulins and by intestinal biopsy, which shows reduced or absent plasma cells and nodular lymphoid hyperplasia.

Management
The underlying cause of small bowel bacterial overgrowth should be addressed, where possible. A course of broad-spectrum antibiotic for 2 weeks is the first-line treatment, although there is no consensus on agent or dose. Examples include tetracycline (250 mg 4 times daily), metronidazole (400 mg 3 times daily), amoxicillin (250 mg 3 times daily) or ciprofloxacin (250 mg twice daily). If breath testing reveals high methane production, addition of neomycin (500 mg twice daily) may be beneficial. Up to 50% of patients do not respond adequately and relapse rates are high. Some patients require up to 4 weeks of treatment and, in a few, continuous rotating courses of antibiotics are necessary. Consideration should be given to the risk of emerging antimicrobial resistance. Intramuscular vitamin B₁₂ supplementation may be needed in chronic cases, as the bacteria utilise vitamin B₁₂. Patients with motility disorders, such as diabetes and systemic sclerosis, can sometimes benefit from antidiarrhoeal drugs (diphenoxylate (5 mg 3 times daily orally) or loperamide (2 mg 4–6 times daily orally). Giardiasis should

*Most commonly caused by Crohn’s disease.

21.45 Malabsorption in old age

- **Coeliac disease**: symptoms such as dyspepsia tend to be vague; only 25% present classically with diarrhoea and weight loss. Metabolic bone disease, folate or iron deficiency, coagulopathy and small bowel lymphoma are more common.
- **Small bowel bacterial overgrowth**: more common due to atrophic gastritis, resulting in hypo- or achlorhydria, increased prevalence of jejunal diverticulosis and long-term adverse effects of gastric surgery for ulcer disease.
be controlled in patients with hypogammaglobulinaemia using metronidazole or tinidazole, but if symptoms fail to respond adequately, immunoglobulin infusions may be required.

### Whipple’s disease

This rare condition is characterised by infiltration of small intestinal mucosa by ‘foamy’ macrophages, which stain positive with periodic acid–Schiff (PAS) reagent. The disease is a multisystem one and almost any organ can be affected, sometimes long before gastrointestinal involvement becomes apparent (Box 21.46).

#### Pathophysiology

Whipple’s disease is caused by infection with the Gram-positive bacillus *Tropheryma whipplei*, which becomes resident within macrophages in the bowel mucosa. Villi are widened and flattened, containing densely packed macrophages in the lamina propria, which obstruct lymphatic drainage and cause fat malabsorption.

#### Clinical features

Middle-aged Caucasian men are most frequently affected and presentation depends on the pattern of organ involvement. Low-grade fever is common and most patients have joint symptoms to some degree, often as the first manifestation. Occasionally, neurological manifestations may predominate and CNS involvement is the most serious consequence.

#### Investigations

Diagnosis is made by the characteristic features on small bowel biopsy, with characterisation of the bacillus by polymerase chain reaction (PCR).

#### Management

Whipple’s disease is often fatal if untreated but responds well, at least initially, to intravenous ceftriaxone (2 g daily for 2 weeks), followed by oral co-trimoxazole for at least 1 year. Symptoms usually resolve quickly and biopsy changes revert to normal in a few weeks. Long-term follow-up is essential, as clinical relapse occurs in up to one-third of patients, often within the CNS; in this case, the same therapy is repeated or else treatment with doxycycline and hydroxychloroquine is necessary.

### Bile acid diarrhoea

Bile acid diarrhoea can occur idiopathically (type 1), as a complication of small bowel resection, post cholecystectomy (type 2) or in association with other conditions such as microscopic colitis, chronic pancreatitis, coeliac disease, small intestinal bacterial overgrowth or diabetes mellitus. The population prevalence is estimated at around 1% and the disease is often under-diagnosed. It is now appreciated that many patients diagnosed with diarrhoea-predominant irritable bowel syndrome have evidence of bile acid diarrhoea. The most common scenario is in patients with Crohn’s disease who have undergone ileal resection, which can also lead to other malabsorptive manifestations (Fig. 21.43). Unabsorbed bile salts pass into the colon, stimulating water and electrolyte secretion and causing diarrhoea. If hepatic synthesis of new bile acids cannot keep pace with faecal losses, fat malabsorption occurs. Another consequence is the formation of lithogenic bile, leading to gallstones. Renal calculi, rich in oxalate, develop. Normally, oxalate in the colon is bound to and precipitated by calcium. Unabsorbed bile salts preferentially bind calcium, leaving oxalate to be absorbed, with development of urinary oxalate calculi.

Patients have urgent watery diarrhoea or mild steatorrhoea. Contrast studies and tests of B₄ and bile acid absorption, such as the ⁷⁵Se-homocholic acid taurine (SeHCAT) test (p. 777), are useful investigations but are not available throughout the world due to use of synthetic radio-labelled compound. An elevated serum 7α-hydroxycholestenone is a useful non-invasive marker of bile acid diarrhoea. Diarrhoea usually responds well to bile acid sequestrants, such as colestyramine or colesevelam, which bind bile salts in the intestinal lumen. Aluminium hydroxide can be used as an alternative.

### Short bowel syndrome

This is discussed in detail on page 708.

### Radiation enteritis and proctocolitis

Intestinal damage occurs in 10–15% of patients undergoing radiotherapy for abdominal or pelvic malignancy. The risk varies with total dose, dosing schedule and the use of concomitant chemotherapy.

#### Pathophysiology

The rectum, sigmoid colon and terminal ileum are most frequently involved. Radiation causes acute inflammation, shortening of villi, oedema and crypt abscess formation. These usually resolve completely but some patients develop an obliteratorative endarteritis affecting the endothelium of submucosal arterioles over 2–12 months. In the longer term, this can provoke a fibrotic reaction, leading to adhesions, ulceration, strictures, obstruction or fistula to adjacent organs.

#### Clinical features

In the acute phase, there is nausea, vomiting, cramping abdominal pain and diarrhoea. When the rectum and colon are involved, rectal mucus, bleeding and tenesmus occur. The chronic phase develops after 5–10 years in some patients and produces one or more of the problems listed in Box 21.47.
It leads to fat malabsorption and deficiency of fat-soluble vitamins. Jejunal biopsy reveals enterocytes distended with resynthesised triglyceride and normal villous morphology. Serum cholesterol and triglyceride levels are low. A number of other abnormalities occur in this syndrome, including acanthocytosis, retinitis pigmentosa and a progressive neurological disorder with cerebellar and dorsal column signs. Symptoms may be improved by a low-fat diet supplemented with medium-chain triglycerides and vitamins A, D, E and K.

Motility disorders

Chronic intestinal pseudo-obstruction

Small intestinal motility is disordered in conditions that affect the smooth muscle or nerves of the intestine. Many cases are ‘primary’ (idiopathic), while others are ‘secondary’ to a variety of disorders or drugs (Box 21.48).

Clinical features

There are recurrent episodes of nausea, vomiting, abdominal discomfort and distension, often worse after food. Alternating constipation and diarrhoea occur and weight loss results from malabsorption (due to bacterial overgrowth) and fear of eating. There may also be symptoms of dysmotility affecting other parts of the gastrointestinal tract, such as dysphagia, and features of bladder dysfunction in primary cases. Some patients develop severe abdominal pain for reasons that are poorly understood and this can be difficult to manage.

Investigations

The diagnosis is often delayed and a high index of suspicion is needed. Plain X-rays show distended loops of bowel and air-fluid levels but barium studies demonstrate no mechanical obstruction. Laparotomy is sometimes required to exclude obstruction and to obtain full-thickness biopsies of the intestine. Examination of biopsy material using specialised techniques, such as electron microscopy, and immunohistochemistry can diagnose the many
rare diseases of enteric smooth muscle and nerves that can cause this syndrome.

**Management**

This is often difficult. Underlying causes should be addressed and further surgery avoided. Metoclopramide or domperidone may enhance motility and antibiotics are given for bacterial overgrowth. Nutritional and psychological support is also necessary.

**Miscellaneous disorders of the small intestine**

**Protein-losing enteropathy**

This term is used when there is excessive loss of protein into the gut lumen, sufficient to cause hypoproteinaemia. Protein-losing enteropathy occurs in many gut disorders but is most common in those in which ulceration occurs (Box 21.49). In other disorders, protein loss can result from increased mucosal permeability or obstruction of intestinal lymphatic vessels. Patients present with peripheral oedema and hypoproteinaemia in the presence of normal liver function, low albumin and globulin, and without proteinuria. The diagnosis can be confirmed by measurement of faecal clearance of α1-antitrypsin or 51Cr-labelled albumin after intravenous injection. Other investigations should be performed to determine the underlying cause. Treatment is that of the underlying disorder, with nutritional support and measures to control peripheral oedema.

**Intestinal lymphangiectasia**

This may be primary, resulting from congenital malunion of lymphatics, or secondary to lymphatic obstruction due to lymphoma, filariasis or constrictive pericarditis. Impaired drainage of intestinal lymphatic vessels leads to discharge of protein and fat-rich lymph into the gastrointestinal lumen. The condition presents with peripheral lymphoedema, pleural effusions or chylous ascites, and steatorrhoea. Investigations reveal hypoalbuminaemia, lymphopenia and reduced serum immunoglobulin concentrations. The diagnosis can be made by CT scanning and by enteroscopy with jejunal biopsy, which shows greatly dilated lacteals. Treatment consists of a low-fat diet with medium-chain triglyceride supplements.

**Ulceration of the small intestine**

Small bowel ulcers are uncommon and are either idiopathic or secondary to underlying intestinal disorders (Box 21.50). Ulcers are more common in the ileum and cause bleeding, perforation, stricture formation or obstruction. Barium studies and enteroscopy confirm the diagnosis.

**NSAID-associated small intestinal toxicity**

These drugs cause a spectrum of small intestinal lesions ranging from erosions and ulcers to mucosal webs, strictures and, rarely, a condition known as ‘diaphragm disease’, in which intense submucosal fibrosis results in circumferential strictureting. The condition can present with pain, obstruction, bleeding or anaemia, and may mimic Crohn’s disease, carcinoma or lymphoma. Enteroscopy or capsule endoscopy can reveal the diagnosis but sometimes this is discovered only at laparotomy.

**Eosinophilic gastroenteritis**

This disorder of unknown aetiology can affect any part of the gastrointestinal tract; it is characterised by eosinophil infiltration involving the gut wall, in the absence of parasitic infection or eosinophilia of other tissues. It may be mucosal, muscular or subserosal. Peripheral blood eosinophilia is present in 80% of cases.

**Clinical features**

There are features of obstruction and inflammation, such as colicky pain, nausea and vomiting, diarrhoea and weight loss. Protein-losing enteropathy occurs and up to 50% of patients have a history of other allergic disorders. Serosal involvement may produce eosinophilic ascites.

**Investigations and management**

The diagnosis is made by histological assessment of multiple endoscopic biopsies, although full-thickness biopsies are occasionally required. Other investigations should be performed.
to exclude parasitic infection and other causes of eosinophilia. The serum IgE concentration is often raised. Dietary manipulations are rarely effective, although elimination diets, especially of milk, may benefit a few patients. Severe symptoms are treated with prednisolone (20–40 mg daily) and/or sodium cromoglicate, which stabilises mast cell membranes. The prognosis is good in the majority of patients.

### Meckel's diverticulum

This is the most common congenital anomaly of the gastrointestinal tract and occurs in 0.3–3% of people, but the vast majority of affected individuals are asymptomatic throughout life. The diverticulum results from failure of closure of the vitelline duct, with persistence of a blind-ending sac arising from the anterior mesenteric border of the ileum; it usually occurs within 100 cm of the ileocaecal valve and is up to 5 cm long. Approximately 50% contain ectopic gastric mucosa; rarely, colonic, pancreatic or endometrial tissue is present. Complications most commonly occur in the first 2 years of life but are occasionally seen in young adults. Bleeding can result from ulceration of ileal mucosa adjacent to the ectopic parietal cells and presents as recurrent melena or altered blood per rectum. The diagnosis can be made by scanning the abdomen using a gamma counter following an intravenous injection of 99mTc-pertechnetate, which is concentrated by ectopic parietal cells. Other complications include intestinal obstruction, diverticulitis, intussusception and perforation. Intervention is unnecessary unless complications occur.

### Adverse food reactions

Adverse food reactions are common and are subdivided into food intolerance and food allergy, the former being much more common. In food intolerance, there is an adverse reaction to food that is not immune-mediated and results from pharmacological (histamine, tyramine or monosodium glutamate), metabolic (lactase deficiency) or other mechanisms (toxins or chemical contaminants in food).

### Lactose intolerance

Human milk contains around 200 mmol/L (68 g/L) of lactose, which is normally digested to glucose and galactose by the brush border enzyme lactase prior to absorption. In most populations, enterocyte lactase activity declines throughout childhood. The enzyme is deficient in up to 90% of adult Africans, Asians and South Americans but only 5% of northern Europeans.

In cases of genetically determined (primary) lactase deficiency, jejunal morphology is normal. ‘Secondary’ lactase deficiency occurs as a consequence of disorders that damage the jejunal mucosa, such as coeliac disease and viral gastroenteritis. Unhydrolysed lactose enters the colon, where bacterial fermentation produces volatile short-chain fatty acids, hydrogen and carbon dioxide.

**Clinical features**

In most people, lactase deficiency is completely asymptomatic. However, some complain of colicky pain, abdominal distension, increased flatus, borborygmi and diarrhoea after ingesting milk or milk products. Irritable bowel syndrome may be suspected but the correct diagnosis is suggested by clinical improvement on lactose withdrawal. The lactose hydrogen breath test is a useful non-invasive investigation.

Dietary exclusion of lactose is recommended, although most sufferers are able to tolerate small amounts of milk without symptoms. Addition of commercial lactase preparations to milk has been effective in some studies but is costly.

### Intolerance of other sugars

‘Osmotic’ diarrhoea can be caused by sorbitol, an unabsorbable carbohydrate that is used as an artificial sweetener. Fructose contained within fruit juices may also cause diarrhoea if it is consumed in greater quantities than can be absorbed.

### Food allergy

Food allergies are immune-mediated disorders, most commonly due to type I hypersensitivity reactions with production of IgE antibodies, although type IV delayed hypersensitivity reactions are also seen (p. 80). Up to 20% of the population perceive themselves as suffering from food allergy but only 1–2% of adults and 5–7% of children have genuine food allergies. The most common culprits are peanuts, milk, eggs, soya and shellfish.

Clinical manifestations occur immediately on exposure and range from trivial to life-threatening or even fatal anaphylaxis. The common oral allergy syndrome results from contact with benzoic acid in certain fresh fruit juices, leading to urticaria and angioedema of the lips and oropharynx. This is not, however, an immune-mediated reaction. ‘Allergic gastroenteropathy’ has features similar to eosinophilic gastroenteritis, while ‘gastrointestinal anaphylaxis’ consists of nausea, vomiting, diarrhoea and sometimes cardiovascular and respiratory collapse. Fatal reactions to trace amounts of peanuts are well documented.

The diagnosis of food allergy is difficult to prove or refute. Skin-prick tests and measurements of antigen-specific IgE antibodies in serum have limited predictive value. Double-blind placebo-controlled food challenges are the gold standard but are laborious and are not readily available. In many cases, clinical suspicion and trials of elimination diets are used.

Treatment of proven food allergy consists of detailed patient education and awareness, strict elimination of the offending antigen, and, in some cases, antihistamines or sodium cromoglicate. Anaphylaxis should be treated as a medical emergency with resuscitation, airway support and intravenous adrenaline (epinephrine). Teachers and other carers of affected children should be trained to deal with this. Patients should wear an information bracelet and be taught to carry and use a preloaded adrenaline syringe.

### Infections of the small intestine

#### Travellers’ diarrhoea, giardiasis and amoebiasis

See pages 232, 287 and 286.

#### Abdominal tuberculosis

*Mycobacterium tuberculosis* is a rare cause of abdominal disease in Caucasians but must be considered in people in and from the developing world and in AIDS patients. Gut infection usually results from human *M. tuberculosis*, which is swallowed after coughing. Many patients have no pulmonary symptoms and a normal chest X-ray.

The area most commonly affected is the ileocaecal region. The presentation and radiological findings may be very similar to those of Crohn’s disease. Abdominal pain can be acute or of several months’ duration but diarrhoea is less common in tuberculosis.
than in Crohn’s disease. Low-grade fever is common but not invariable. Like Crohn’s disease, tuberculosis can affect any part of the gastrointestinal tract and perianal disease with fistula is recognised. Peritoneal tuberculosis may result in peritonitis with exudative ascites, associated with abdominal pain and fever. Granulomatous hepatitis occurs.

**Investigations**

Abdominal tuberculosis causes an elevated ESR; a raised serum alkaline phosphatase concentration suggests hepatic involvement. Histological proof should be sought by endoscopy, laparoscopy or liver biopsy. Caseation of granulomas is not always seen and acid- and alcohol-fast bacteria are often scanty. Culture may be helpful but identification of the organism may take 6 weeks and diagnosis is now possible on biopsy specimens using PCR-based techniques.

**Management**

When the presentation is very suggestive of abdominal tuberculosis, chemotherapy with multiple anti-tuberculous drugs should be commenced, even if bacteriological or histological proof is lacking. Isoniazid, pyrazinamide and ethambutol is a common standard regime (p. 590), though the precise choice will be dependent on local drug resistance patterns.

---

**Cryptosporidiosis**

Cryptosporidiosis and other protozoal infections, including cystoisosporiasis (Cystoisospora belli) and microsporidiosis, are dealt with on pages 287 and 317.

---

**Tumours of the small intestine**

The small intestine is rarely affected by neoplasia and fewer than 5% of all gastrointestinal tumours occur at this site.

**Benign tumours**

The most common are adenomas, GISTs, lipomas and hamartomas. Adenomas are most often found in the periamplary region and are usually asymptomatic, although occult bleeding or obstruction due to intussusception may occur. Transformation to adenocarcinoma is rare. Multiple adenomas are common in the duodenum of patients with familial adenomatous polyposis (FAP), who merit regular endoscopic surveillance. Hamartomatous polyps with almost no malignant potential occur in Peutz–Jeghers syndrome (p. 829).

**Malignant tumours**

These are rare and include, in decreasing order of frequency, adenocarcinoma, neuro-endocrine tumours, malignant GIST and lymphoma. The majority occur in middle age or later. Kaposi’s sarcoma of the small bowel may arise in patients with AIDS.

**Adenocarcinomas**

Adenocarcinomas occur with increased frequency in patients with FAP, coeliac disease, small bowel Crohn’s disease and Peutz–Jeghers syndrome. This is a rare cancer, accounting for less than 5% of all gastrointestinal malignancies. The non-specific presentation and rarity of these lesions often lead to a delay in diagnosis. Despite advances in imaging and endoscopic techniques, early diagnosis is difficult. Barium follow-through examination or small bowel enterography studies demonstrate most lesions of this type. Enteroscopy, capsule endoscopy, mesenteric angiography and CT also play a role in investigation. Treatment is by surgical resection.

**Neuro-endocrine tumours**

These are discussed in detail on page 678.

**Lymphoma**

Non-Hodgkin lymphoma (p. 964) may involve the gastrointestinal tract as part of more generalised disease or may rarely arise in the gut, the small intestine being most commonly affected. Lymphomas occur with increased frequency in patients with coeliac disease, HIV/AIDS and other immunodeficiency states. Most are of B-cell origin, although lymphoma associated with coeliac disease is derived from T cells (enteropathy-associated T-cell lymphoma).

Colicky abdominal pain, obstruction and weight loss are the presenting features and perforation is also seen occasionally. Malabsorption is a feature of diffuse bowel involvement and hepatosplenomegaly is rare.

The diagnosis is made by small bowel biopsy, radiological contrast studies and CT. Staging investigations should be performed as for lymphomas occurring elsewhere (p. 962). Surgical resection, where possible, is the treatment of choice, with radiotherapy and combination chemotherapy reserved for those with advanced disease. The prognosis depends largely on the stage at diagnosis, cell type, patient age and the presence of “B” symptoms (fever, weight loss, night sweats).

**Immunoproliferative small intestinal disease**

Immunoproliferative small intestinal disease (IPSID), also known as alpha heavy chain disease, is a rare condition occurring mainly in Mediterranean countries, the Middle East, India, Pakistan and North America. It is a variant of B-cell lymphoma of MALT type and often associated with Campylobacter jejuni infection. The condition varies in severity from relatively benign to frankly malignant.

The small intestinal mucosa is diffusely affected, especially proximally, by a dense lymphoplasmacytic infiltrate. Enlarged mesenteric lymph nodes are also common. Most patients are young adults who present with malabsorption, anorexia and fever. Serum electrophoresis confirms the presence of alpha heavy chains (from the F\text{c} \text{portion of IgA}). Prolonged remissions can be obtained with long-term antibiotic therapy but chemotherapy is required for those who fail to respond or who have aggressive disease.

---

**Inflammatory bowel disease**

Ulcerative colitis and Crohn’s disease are chronic inflammatory bowel diseases that pursue a protracted relapsing and remitting course, usually extending over years. The diseases have many similarities and it is sometimes impossible to differentiate between them. One crucial distinction is that ulcerative colitis involves only the colon, while Crohn’s disease can involve any part of the gastrointestinal tract from mouth to anus. A summary of the main features of ulcerative colitis and Crohn’s disease is provided in Box 21.51.

The incidence of inflammatory bowel disease (IBD) varies widely between populations. There was a dramatic increase in the incidence of both ulcerative colitis and Crohn’s disease in the Western world, starting in the second half of the last century and
coinciding with the introduction of a more ‘hygienic’ environment with the advent of domestic refrigeration and the widespread use of antibiotics. The developing world has seen similar patterns, as these countries adopt an increasingly Westernised lifestyle.

In the West, the incidence of ulcerative colitis is stable at 10–20 per 100 000, with a prevalence of 100–200 per 100 000, while the incidence of Crohn’s disease is increasing and is now 5–10 per 100 000, with a prevalence of 50–100 per 100 000. Both diseases most commonly start in the second and third decades of life, with a second smaller incidence peak in the seventh decade. Approximately 240 000 people are affected by IBD in the UK (approximately 1.4 million in the USA), equating to a prevalence of about 1 in 250. Life expectancy in patients with IBD in the UK (approximately 1.4 million in the USA), equating to a prevalence of about 1 in 250. Life expectancy in patients with IBD is similar to that of the general population. Although many patients require surgery and admission to hospital for other reasons, with substantial associated morbidity, the majority have an excellent work record and pursue a normal life.

Pathophysiology

IBD has both environmental and genetic components, and evidence from genome-wide association studies suggests that genetic variants that predispose to Crohn’s disease may have undergone positive selection by protecting against infectious diseases, including tuberculosis (Box 21.52). It is thought that IBD develops because these genetically susceptible individuals mount an abnormal inflammatory response to environmental triggers, such as intestinal bacteria. This leads to inflammation of the intestine with involvement of a wide array of innate and adaptive immune cell responses, with release of inflammatory mediators, including TNF-α, IL-12 and IL-23, which cause tissue damage (Fig. 21.44). There is an association between microbial dysbiosis and IBD. For example, there is a reduced diversity, primarily of Firmicutes and in particular, Faecalibacterium prausnitzii. Functional changes in the bacteria are important and include a reduction of anti-inflammatory metabolites, such as butyrate and other short-chain fatty acids. There is emerging evidence that the virome and mycobiome (fungal species) may be important in the development of IBD. In both diseases, the intestinal wall is infiltrated with acute and chronic inflammatory cells, but there are important differences between the conditions in the distribution of lesions and in histological features (Fig. 21.45).

(5-ASA = 5-aminosalicylic acid; TNF = tumour necrosis factor)
Ulcerative colitis

Inflammation invariably involves the rectum (proctitis) and spreads proximally in a continuous manner to involve the entire colon in some cases (pancolitis). In long-standing pancolitis, the bowel can become shortened and post-inflammatory ‘pseudopolyps’ develop; these are normal or hypertrophied residual mucosa within areas of atrophy (Fig. 21.46). The inflammatory process is limited to the mucosa and spares the deeper layers of the bowel wall (Fig. 21.47). Both acute and chronic inflammatory cells infiltrate the lamina propria and the crypts (‘cryptitis’). Crypt abscesses are typical. Goblet cells lose their mucus and, in long-standing

**Fig. 21.46** Pseudopolyposis in ulcerative colitis.

---

**Fig. 21.44** Pathogenesis of inflammatory bowel disease. (1) Bacterial antigens are taken up by specialised M cells, pass between leaky epithelial cells or enter the lamina propria through ulcerated mucosa. (2) After processing, they are presented to type 1 T-helper cells by antigen-presenting cells (APCs) in the lamina propria. (3) T-cell activation and differentiation results in a Th1 T-cell-mediated cytokine response (4) with secretion of cytokines, including interferon gamma (IFN-γ). Further amplification of T cells perpetuates the inflammatory process with activation of non-immune cells and release of other important cytokines, including interleukin 12 (IL-12), IL-23, IL-1, IL-6 and tumour necrosis factor alpha (TNF-α). These pathways occur in all normal individuals exposed to an inflammatory insult and this is self-limiting in healthy subjects. In genetically predisposed persons, dysregulation of innate immunity may trigger inflammatory bowel disease.

---

**Fig. 21.45** Common patterns of disease distribution in inflammatory bowel disease.
Cases, glands become distorted. Dysplasia, characterised by heaping of cells within crypts, nuclear atypia and increased mitotic rate, may herald the development of colon cancer.

Crohn's disease

The sites most commonly involved are, in order of frequency, the terminal ileum and right side of colon, colon alone, terminal ileum alone, ileum and jejunum. The entire wall of the bowel is oedematous and thickened, and there are deep ulcers that often appear as linear fissures; thus the mucosa between them is described as ‘cobblesone’. These may penetrate through the bowel wall to initiate abscesses or fistulae involving the bowel, bladder, uterus, vagina and skin of the perineum. The mesenteric lymph nodes are enlarged and the mesentery is thickened. Crohn's disease has a patchy distribution and the inflammatory process is interrupted by islands of normal mucosa. On histological examination, the bowel wall is thickened with a chronic inflammatory infiltrate throughout all layers (Fig. 21.48).

Clinical features

Ulcerative colitis

The cardinal symptoms are rectal bleeding with passage of mucus and bloody diarrhoea. The presentation varies, depending on the site and severity of the disease (see Fig. 21.45), as well as the presence of extra-intestinal manifestations. The first attack is usually the most severe and is followed by relapses and remissions. Emotional stress, intercurrent infection, gastroenteritis, antibiotics or NSAID therapy may all provoke a relapse. Proctitis causes rectal bleeding and mucus discharge, accompanied by tenesmus. Some patients pass frequent, small-volume fluid stools, while others pass pellety stools due to constipation upstream of the inflamed rectum. Constitutional symptoms do not occur. Left-sided and extensive colitis causes bloody diarrhoea with mucus, often with abdominal cramps. In severe cases, anorexia, malaise, weight loss and abdominal pain occur and the patient is toxic, with fever, tachycardia and signs of peritoneal inflammation (Box 21.53).

Crohn's disease

The major symptoms are abdominal pain, diarrhoea and weight loss. Ileal Crohn's disease (Figs 21.49 and 21.50) may cause subacute or even acute intestinal obstruction. The pain is often associated with diarrhoea, which is usually watery and does not contain blood or mucus. Almost all patients lose weight because they avoid food, since eating provokes pain. Weight loss may also be due to malabsorption and some patients present with features of fat, protein or vitamin deficiencies. Crohn's colitis presents in an identical manner to ulcerative colitis but rectal

*The Truelove–Witts criteria for acute severe ulcerative colitis are ≥6 bloody stools/24 hrs plus one or more of: anaemia, fever, tachycardia and high inflammatory markers.

Fig. 21.50 Barium follow-through showing terminal ileal Crohn’s disease. A long stricture is present (arrow A), and more proximally there is ulceration with characteristic ‘rose thorn’ ulcers (arrow B).

Sparing and the presence of perianal disease are features that favour a diagnosis of Crohn’s disease. Many patients present with symptoms of both small bowel and colonic disease. A few patients present with isolated perianal disease, vomiting from jejunal strictures or severe oral ulceration.

Physical examination often reveals evidence of weight loss, anaemia with glossitis and angular stomatitis. There is abdominal tenderness, most marked over the inflamed area. An abdominal mass may be palpable and is due to matted loops of thickened bowel or an intra-abdominal abscess. Perianal skin tags, fissures or fistulae are found in at least 50% of patients.

**Differential diagnosis**

The differential diagnosis is summarised in Box 21.54. The most important issue is to distinguish the first attack of acute colitis from infection. In general, diarrhoea lasting longer than 10 days in Western countries is unlikely to be the result of infection, whereas a history of foreign travel, antibiotic exposure (Clostridium difficile/pseudomembranous colitis) or homosexual contact increases the possibility of infection, which should be excluded by the appropriate investigations (see below). The diagnosis of Crohn’s disease is usually more straightforward and is made on the basis of imaging and clinical presentation, but in atypical cases biopsy or surgical resection is necessary to exclude other diseases (Box 21.55).
Complications

Life-threatening colonic inflammation

This can occur in both ulcerative colitis and Crohn’s colitis. In the most extreme cases, the colon dilates (toxic megacolon) and bacterial toxins pass freely across the diseased mucosa into the portal and then systemic circulation. This complication arises most commonly during the first attack of colitis and is recognised by the features described in Box 21.53. An abdominal X-ray should be taken daily because, when the transverse colon is dilated to more than 6 cm (Fig. 21.51), there is a high risk of colonic perforation, although this complication can also occur in the absence of toxic megacolon. Severe colonic inflammation with toxic dilatation is a surgical emergency and most often requires colectomy.

Haemorrhage

Haemorrhage due to erosion of a major artery is rare but can occur in both conditions.

Fistulae

These are specific to Crohn’s disease. Enterocutaneous fistulae can cause diarrhoea and malabsorption due to blind loop syndrome. Enterovesical fistulation causes recurrent urinary infections and pneumaturia. An enterovaginal fistula causes a faeculent vaginal discharge. Fistulation from the bowel may also cause perianal or ischiorectal abscesses, fissures and fistulae.

Cancer

The risk of dysplasia and cancer increases with the duration and extent of uncontrolled colonic inflammation. Thus patients who have long-standing, extensive colitis are at highest risk. Oral mesalazine therapy reduces the risk of dysplasia and neoplasia in ulcerative colitis. Azathioprine also seems to reduce the risk of colorectal cancer in ulcerative colitis and Crohn’s colitis. This protective effect probably extends to any medical treatment that results in sustained healing of the colonic mucosa. The cumulative risk for dysplasia in ulcerative colitis may be as high as 20% after 30 years but is probably lower for Crohn’s colitis. The risk is particularly high in patients who have concomitant primary sclerosing cholangitis for unknown reasons. Tumours develop in areas of dysplasia and may be multiple. Patients with long-standing colitis are therefore entered into surveillance programmes beginning 10 years after diagnosis. Targeted biopsies of areas that show abnormalities on staining with indigo carmine or methylene blue increase the chance of detecting dysplasia and this technique (termed pancolonic chromo-endoscopy) has replaced colonoscopy with random biopsies taken every 10 cm in screening for malignancy. The procedure allows patients to be stratified into high-, medium- or low-risk groups to determine the interval between surveillance procedures. Family history of colon cancer is also an important factor to consider. If high-grade dysplasia is found, panproctocolectomy is usually recommended because of the high risk of colon cancer.

Extra-intestinal complications

Extra-intestinal complications are common in IBD and may dominate the clinical picture. Some of these occur during relapse of intestinal disease; others appear to be unrelated to intestinal disease activity (Fig. 21.52).

Investigations

Investigations are necessary to confirm the diagnosis, define disease distribution and activity, and identify complications. Full blood count may show anaemia resulting from bleeding or malabsorption of iron, folate or vitamin B12. Platelet count can also be high as a marker of chronic inflammation. Serum albumin concentration falls as a consequence of protein-losing enteropathy, inflammatory disease or poor nutrition. ESR and CRP are elevated in exacerbations and in response to abscess formation. Faecal calprotectin has a high sensitivity for detecting gastrointestinal inflammation and may be elevated, even when the CRP is normal. It is particularly useful for distinguishing inflammatory bowel disease from irritable bowel syndrome at diagnosis, and for subsequent monitoring of disease activity.

Bacteriology

At initial presentation, stool microscopy, culture and examination for Clostridium difficile toxin or for ova and cysts, blood cultures and serological tests should be performed. These investigations should be repeated in established disease to exclude superimposed enteric infection in patients who present with exacerbations of IBD. During acute flares necessitating hospital admission, three separate stool samples should be sent for bacteriology to maximise sensitivity.

Endoscopy

Patients who present with diarrhoea plus raised inflammatory markers or alarm features, such as weight loss, rectal bleeding and anaemia, should undergo ileocolonoscopy. Flexible sigmoidoscopy is occasionally performed to make a diagnosis, especially during acute severe presentations when ileocolonoscopy may confer an unacceptable risk; ileocolonoscopy should still be performed at a later date, however, in order to evaluate disease extent. In ulcerative colitis, there is loss of vascular pattern, granularity, friability and contact bleeding, with or without ulceration (Fig. 21.53). In Crohn’s disease, patchy inflammation, with discrete, deep ulcers, strictures and perianal disease (fissures, fistulae and skin tags), is typically observed, often with rectal sparing. In established disease, colonoscopy may show active inflammation

Fig. 21.51 Plain abdominal X-ray showing a grossly dilated colon due to severe ulcerative colitis. There is also marked mucosal oedema and ‘thumb-printing’ (arrows).

with pseudopolyps or a complicating carcinoma. Biopsies should be taken from each anatomical segment (terminal ileum, right colon, transverse colon, left colon and rectum) to confirm the diagnosis and define disease extent, and also to seek dysplasia in patients with long-standing colitis guided by pancolonic chromo-endoscopy. In Crohn’s disease, wireless capsule endoscopy is useful in the identification of small bowel inflammation but should be avoided in the presence of strictures. Enteroscopy may be required to make a histological diagnosis of small bowel Crohn’s disease, when the inflamed segment is out of reach of standard endoscopes. All children and most adults with Crohn’s disease should have upper gastrointestinal endoscopy and biopsy to complete their staging. Not only is upper gastrointestinal Crohn’s disease relatively common in this group, but also it may help to make a definitive diagnosis in patients who otherwise appear to have non-specific colonic inflammation.

Radiology

Barium enema is a less sensitive investigation than colonoscopy in patients with colitis and, where colonoscopy is incomplete, a CT colonogram is preferred. Small bowel imaging is essential to complete staging of Crohn’s disease. Traditional contrast imaging by barium follow-through demonstrates affected areas of the bowel as narrowed and ulcerated, often with multiple strictures (see Fig. 21.50). This has largely been replaced now by MRI enterography, which does not involve exposure to radiation and is a sensitive way of detecting extra-intestinal manifestations and of assessing pelvic and perineal involvement. These studies use an orally administered small bowel-distending agent and intravenous contrast to provide transmural imaging that can usefully distinguish between predominantly inflammatory strictures (that should respond to anti-inflammatory medical strategies)
and fibrotic strictures (that require a mechanical solution, such as surgical resection, strictureplasty or endoscopic balloon dilatation). A plain abdominal X-ray is essential in the management of patients who present with severe active disease. Dilatation of the colon (see Fig. 21.51), mucosal oedema (thumb-printing) or evidence of perforation may be found. Patients with proctitis may have features of proximal faecal loading. In small bowel Crohn’s disease, there may be evidence of intestinal obstruction or displacement of bowel loops by a mass. Ultrasound is a very powerful tool to detect small bowel inflammation and stricture formation but it is operator-dependent. The role of CT is limited to screening for complications, such as perforation or abscess formation, in the acutely unwell.

**Management**

Drugs that are used in the treatment of IBD are listed in Box 21.56. Although medical therapy plays an important role, optimal management depends on establishing a multidisciplinary team-based approach involving physicians, surgeons, radiologists, nurse specialists and dietitians. Both ulcerative colitis and Crohn’s disease are life-long conditions and have important psychosocial implications; specialist nurses, counsellors and patient support groups have key roles in education, reassurance and coping. The key aims of medical therapy are to:

- treat acute attacks (induce remission)
- prevent relapses (maintain remission)
- prevent bowel damage
- detect dysplasia and prevent carcinoma
- select appropriate patients for surgery.

**Ulcerative colitis**

Active proctitis Most patients with ulcerative proctitis respond to a 1 g mesalazine suppository but some will additionally require oral 5-aminosalicylate (5-ASA) therapy. Topical glucocorticoids are less effective and are reserved for patients who are intolerant of topical mesalazine. Patients with resistant disease may require treatment with systemic glucocorticoids and immunosuppressants. A stool softener may be required to treat proximal constipation.

Active left-sided or extensive ulcerative colitis In mild to moderately active cases, the combination of a once-daily oral and a topical 5-ASA preparation ("top and tail approach") is usually effective. The topical preparation (1 g foam or liquid enema) is typically withdrawn after 1 month. The oral 5-ASA is continued long-term to prevent relapse and minimise the risk of dysplasia. In patients who do not respond to this approach within 2–4 weeks, oral prednisolone (40 mg daily, tapered by 5 mg/week over an 8-week total course) is indicated. Glucocorticoids should never be used for maintenance therapy. At the first signs of glucocorticoid resistance (lack of efficacy) or in patients who require recurrent glucocorticoid doses to maintain control, immunosuppressive therapy with a thiopurine should be introduced. Simultaneous calcium and vitamin D supplementation should be given along with glucocorticoids for bone protection.

Severe ulcerative colitis Patients who fail to respond to maximal oral therapy and those who present with acute severe colitis (meeting the Truelove–Witts criteria; see Box 21.53) are best managed in hospital and should be monitored jointly by a physician and surgeon:

- clinically: for the presence of abdominal pain, temperature, pulse rate, stool blood and frequency

**Crohn’s disease**

**Principles of treatment** Crohn’s disease is a progressive condition that may result in stricture or fistula formation if suboptimally treated. It is therefore important to agree long-term treatment goals with the patient; these are to induce remission and then maintain glucocorticoid-free remission with a normal quality of life. Treatment should focus on monitoring the patient carefully for evidence of disease activity and complications (Box 21.58), and ensuring that mucosal healing is achieved.

**Induction of remission** Glucocorticoids remain the mainstay of treatment for active Crohn’s disease. The drug of first choice in patients with ileal disease is budesonide, since it undergoes 90% first-pass metabolism in the liver and has very little systemic toxicity. A typical regimen is 9 mg once daily for 6 weeks, with a gradual reduction in dose over the subsequent 2 weeks when therapy is stopped. If there is no response to budesonide within 2 weeks, the patient should be switched to prednisolone, which has greater potency. This is typically given in a dose of 40 mg daily, reducing by 5 mg/week over 8 weeks, at which point treatment is stopped. Oral prednisolone in the dose regimen described above is the treatment of choice for inducing remission by laboratory testing: haemoglobin, white cell count, albumin, electrolytes, ESR and CRP, stool culture

Radiologically: for colonic dilatation on plain abdominal X-rays.

All patients should be given supportive treatment with intravenous fluids to correct dehydration and enteral nutritional support should be provided for malnourished patients (Box 21.57). Intravenous glucocorticoids (methylprednisolone 60 mg or hydrocortisone 400 mg/day) should be given by intravenous infusion or bolus injection. Topical and oral aminosalicylates have no role to play in the acute severe attack. Response to therapy is judged over the first 3 days. Patients who do not respond promptly to glucocorticoids should be considered for medical rescue therapy with ciclosporin (intravenous infusion or oral) or infliximab (5 mg/kg), which can avoid the need for urgent colectomy in approximately 60% of cases.

Patients who develop colonic dilatation (>6 cm), whose clinical and laboratory measurements deteriorate and those who do not respond after 7–10 days’ maximal medical treatment usually require urgent colectomy. Subtotal colectomy can also be performed laparoscopically, given sufficient local expertise. The surgical and medical teams should liaise early in the disease course and, if possible, the patient should have the opportunity to speak with the stoma nurse prior to colectomy.

**Maintenance of remission** Life-long maintenance therapy is recommended for all patients with left-sided or extensive disease but is not necessary in those with proctitis (although 20% of these patients will develop proximal ‘extension’ over the lifetime of their disease). Once-daily oral 5-aminosalicylates are the preferred first-line agents. Sulfasalazine has a higher incidence of side-effects but is equally effective and can be considered in patients with coexistent arthropathy. Patients who frequently relapse despite aminosalicylate drugs should be treated with thiopurines (azathioprine or 6-mercaptopurine). Biologic therapy with anti-TNF antibodies (infliximab or adalimumab) or anti-α4β7 integrin antibodies (vedolizumab) can also be considered for maintenance treatment in patients with moderate to severe ulcerative colitis who are intolerant of or non-responsive to thiopurine immunosuppression.
### 21.56 Drugs used in the treatment of inflammatory bowel disease

<table>
<thead>
<tr>
<th>Class</th>
<th>Mechanism of action</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aminosalicylates (mesalazine (Asacol, Salofalk, Pentasa, Mezavant), olsalazine, sulfasalazine, balsalazide)</td>
<td>Modulate cytokine release from mucosa / Different means of delivery to colon: pH-dependent (Asacol, Salofalk) / time-dependent (Pentasa) / bacterial breakdown by colonic bacteria from a carrier molecule (sulfasalazine, balsalazide)</td>
<td>No proven value in CD / Available as oral or topical (enema/suppository) / Sulfasalazine causes side-effects in 10–45%: headache, nausea, diarrhea, blood dyscrasias / Other aminosalicylates better tolerated; diarrhea, headache in 2–5% / Rarely, renal impairment (check urea and electrolytes 6-monthly)</td>
</tr>
<tr>
<td>Glucocorticoids (prednisolone, hydrocortisone, budesonide)</td>
<td>Anti-inflammatory / Budesonide is a potent glucocorticoid efficiently cleared from circulation by liver, thereby minimising adrenocortical suppression and steroid side-effects</td>
<td>Topical, oral or IV, according to disease severity / Budesonide considered for active ileitis and ileocolitis / High vigilance for complications / Never used for maintenance therapy / Calcium/vitamin D supplements</td>
</tr>
<tr>
<td>Thiopurines (azathioprine, mercaptopurine)</td>
<td>Immunosuppression by inducing T-cell apoptosis / Azathioprine is metabolised in liver to mercaptopurine, then by TPMT to thioguanine nucleotides</td>
<td>Effective 12 weeks after starting therapy / Complications leading to drug withdrawal in approximately 20%: influenza-like syndrome with myalgia, nausea and vomiting; leucopenia in 3%, particularly in inherited TPMT deficiency; hepatotoxicity; pancreatitis / 60% of those intolerant of azathioprine will tolerate mercaptopurine / Increase in lymphoma (approximately 2–3-fold) and non-melanoma skin cancer (life-long sun protection advised) / Check TPMT levels prior to starting treatment and avoid if deficient/very low due to risk of toxicity / Metabolite levels can be measured to tailor therapy / Use with caution for patients presenting over the age of 60 years due to risk of malignancy</td>
</tr>
<tr>
<td>Methotrexate</td>
<td>Anti-inflammatory</td>
<td>Intolerance in 10–18% / Maximal efficacy when given by SC injection once weekly / Nausea, stomatitis, diarrhea, hepatotoxicity and pneumonitis / Co-prescription of folic acid and antimetabolites. / Teratogenic; robust contraception required for males and females</td>
</tr>
<tr>
<td>Ciclosporin</td>
<td>Inhibits T-cell activation</td>
<td>Rescue therapy to prevent surgery in UC responding poorly to glucocorticoids. No value in CD / Major side-effects in 0–17%: nephrotoxicity, infections, neurotoxicity (including fits) / Minor complications in up to 50%: tremor, paraesthesiae, abnormal liver function tests, hirsutism</td>
</tr>
<tr>
<td>Anti-TNF antibodies (infliximab and adalimumab)</td>
<td>Suppress inflammation and induce apoptosis of inflammatory cells</td>
<td>Moderate to severe CD, including fistulating disease / Moderate to severe UC and acute severe UC as rescue therapy / Acute (anaphylactic) and delayed (serum sickness) infusion reactions after multiple infusions; anti-drug antibody titres and drug levels can be measured / Contraindicated in infection; reactivation of latent tuberculosis and moderate to severe cardiac failure / Increased risk of infections and possibly of malignancy / Rarely, neurological adverse events / Requires assessment for latent tuberculosis and hepatitis B and C prior to commencement / Continue until treatment failure or 12 months and reassess</td>
</tr>
<tr>
<td>Anti-α4β7 integrin (vedolizumab)</td>
<td>Blocks integrin expressed on leukocytes and inhibits interaction with gut-specific receptor on endothelium, reducing leukocyte migration to gut mucosa</td>
<td>Moderate to severe CD or moderate to severe UC where treatment with anti-TNF has failed or is not tolerated / Side-effects include nasopharyngitis, arthralgia, headache / Progressive multifocal leuкоencephalopathy risk is reduced due to gut specificity / Induction with 300 mg infusion at weeks 0, 2 and 6; maintenance 8-weekly infusions thereafter / Discontinue if no improvement after 14 weeks / Continue until treatment failure or 12 months and reassess</td>
</tr>
<tr>
<td>Antibiotics</td>
<td>Antibacterial</td>
<td>Useful in perianal CD and pouchitis / Major concern is peripheral neuropathy with long-term metronidazole</td>
</tr>
<tr>
<td>Antidiarrhoeal agents (loperamide, co-phenoxylate)</td>
<td>Reduce gut motility and small bowel secretion / Loperamide improves anal function</td>
<td>Avoided in acute flare-ups of disease / May precipitate colonic dilatation</td>
</tr>
</tbody>
</table>

(IV = intravenous; SC = subcutaneous; TNF = tumour necrosis factor; TPMT = thiopurine methyltransferase; UC = ulcerative colitis)
in colonic Crohn’s disease. Calcium and vitamin D supplements should be co-prescribed in patients who are on glucocorticoids, to try to compensate for their inhibitory effect on intestinal calcium absorption.

As an alternative to glucocorticoid therapy, enteral nutrition with either an elemental (constituent amino acids) or polymeric (liquid protein) diet may induce remission. Both types of diet are equally effective but the polymeric one is more palatable when taken by mouth. It is particularly effective in children, in whom equal efficacy to glucocorticoids has been demonstrated, and in extensive ileal disease in adults. As well as resting the gut and providing excellent nutritional support, it also has a direct anti-inflammatory effect. It is an effective bridge to urgent staging investigations at first presentation and can be given by mouth or by nasogastric tube. With sufficient explanation, encouragement and motivation, most patients will tolerate it well.

Some individuals with severe colonic disease require admission to hospital for intravenous glucocorticoids. In severe ileal or panenteric disease, induction therapy with an anti-TNF agent is appropriate, provided that acute perforating complications, such as abscesses, have not arisen. Both infliximab and adalimumab are licensed for use in the UK. Randomised trials have demonstrated that combination therapy with an anti-TNF antibody and a thiopurine is the most effective strategy for inducing and maintaining remission in luminal Crohn’s patients. This strategy is more effective than anti-TNF monotherapy, which, in turn, is more effective than thiopurine monotherapy. Following induction of remission, a substantial proportion of patients (20–30%) remain well without the requirement for maintenance therapy. Patients with evidence of persistently active disease require further treatment (see below).

**Maintenance therapy** Immunosuppressive treatment with thiopurines (azathioprine and mercaptopurine) forms the core of maintenance therapy but methotrexate is also effective and can be given once weekly, either orally or by subcutaneous injection. Women and men of child-bearing potential who are prescribed methotrexate must use a robust contraceptive method, and should be counselled to plan pregnancy with a 3-month methotrexate-free period prior to conception since it is teratogenic. Combination therapy with an immunosuppressant and an anti-TNF antibody is the most effective strategy but costs are high and there is an increased risk of serious adverse effects. In the UK, the use of anti-TNF therapy is limited to specific patient subgroups with severe disease (Box 21.59). Vedolizumab is a possible option in patients who have not responded to anti-TNF therapy. It is a humanised monoclonal antibody against α4β7 integrin. The α4β7 is expressed on a specific subset of CD4 leucocytes; vedolizumab binds to this integrin and blocks interaction with MAdCAM-1, expressed on gut endothelial cells, resulting in a reduced influx of immune cells to the inflamed gut mucosa. Serious systemic adverse effects, including progressive multifocal leukoencephalopathy, have been seen with other anti-integrin drugs (such as natalizumab) but this has not emerged with vedolizumab due to its gut specificity. Emerging novel medical therapies for Crohn’s disease are currently in phase III clinical trials and are likely to be available for clinical use in the near future. These include ustekinumab (anti-p40, inhibiting both IL-12 and IL-23) and tofacitinib (a Janus kinase inhibitor that blocks pro-inflammatory cytokine signalling).

Cigarette smokers with Crohn’s disease should be strongly counselled to stop smoking at every possible opportunity. Those that do not manage to stop smoking fare much worse, with increased rates of relapse and surgical intervention. Careful monitoring of disease activity (see Box 21.58) is the key to maintaining sustained remission and preventing the accumulation of bowel damage in Crohn’s disease.
**Fistulae and perianal disease** Fistulae may develop in relation to active Crohn’s disease and are often associated with sepsis. The first step is to define the site by imaging (usually MRI of the pelvis). Surgical exploration by an examination under anaesthetic is usually then required, to delineate the anatomy and drain abscesses. Seton sutures can be inserted through fistula tracts to ensure adequate drainage and to prevent future sepsis. Glucocorticoids are ineffective. Use of antibiotics, such as metronidazole and/or ciprofloxacin, can aid healing as an adjunctive treatment. Thiopurines can be used in chronic disease but do not usually result in fistula healing. Infliximab and adalimumab can heal fistulae and perianal disease in many patients and are indicated when the measures described above have been ineffective. Other options for refractory perianal disease are proctectomy or diverting colostomy.

**Surgical treatment**

**Ulcerative colitis**

Up to 60% of patients with extensive ulcerative colitis eventually require surgery. The indications are listed in Box 21.60. Impaired quality of life, with its impact on occupation and social and family life, is the most important of these. Surgery involves removal of the entire colon and rectum, and cures the patient. One-third of those with pancolitis undergo colectomy within 5 years of diagnosis. Before surgery, patients must be counselled by doctors, stoma nurses and patients who have undergone similar surgery. The choice of procedure is either panproctocolectomy with ileostomy, or proctocolectomy with ileo–anal pouch anastomosis. The sister text to this book, Principles and Practice of Surgery, should be consulted for further details.

**Crohn’s disease**

The indications for surgery are similar to those for ulcerative colitis. Operations are often necessary to deal with fistulae, abscesses and perianal disease, and may also be required to relieve small or large bowel obstruction. In contrast to ulcerative colitis, surgery is not curative and disease recurrence is the rule. The only method that has consistently been shown to reduce post-operative recurrence is smoking cessation. Antibiotics are effective in the short term only. Use of thiopurines post-surgery is suggested if there are indicators of a high chance of recurrence, i.e. more than one resection or evidence of penetrating disease, such as fistulae or abscesses. Otherwise, it is common to undertake colonoscopy 6 months after surgery to inspect and biopsy the anastomosis and neo-terminal ileum. Patients with endoscopic recurrence are then prescribed thiopurines.

Surgery should be as conservative as possible in order to minimise the loss of viable intestine and to avoid the creation of a short bowel syndrome (p. 708). Obstructing or fistulating small bowel disease may require resection of affected tissue. Patients who have localised segments of Crohn’s colitis may be managed by segmental resection and/or multiple stricturoplasties, in which the stricture is not resected but instead incised in its longitudinal axis and sutured transversely. Others who have extensive colitis require total colectomy but ileo–anal pouch formation should be avoided because of the high risk of recurrence within the pouch and subsequent fistulae, abscess formation and pouch failure. Historical datasets show that around 80% of Crohn’s patients undergo surgery at some stage and 70% of these require more than one operation during their lifetime. Clinical recurrence following resectional surgery is present in 50% of all cases at 10 years. Emerging data demonstrate that aggressive medical therapy, coupled with intense monitoring, probably reduces the requirement for surgery substantially.

**IBD in special circumstances**

**Childhood**

Chronic ill health in childhood or adolescent IBD may result in loss of time from education, metabolic bone disease and delayed puberty. Loss of schooling and social contact, as well as frequent hospitalisation, can have important psychosocial consequences. Treatment is similar to that described for adults and may require glucocorticoids, immunosuppressive drugs, biological agents and surgery. Monitoring of height, weight and sexual development is crucial. Children with IBD should be managed by specialised paediatric gastroenterologists and transitioned to adult care in dedicated clinics (Box 21.61).

**Pregnancy**

A women’s ability to become pregnant is adversely affected by active IBD. Pre-conceptual counselling should focus on optimising disease control. During pregnancy, the rule of thirds applies: roughly one-third of women improve, one-third get worse and one-third remain stable with active disease. In the post-partum period, these changes sometimes reverse spontaneously. Drug therapy, including aminosalicylates, glucocorticoids and

**21.61 Inflammatory bowel disease in adolescence**

- **Delayed growth and pubertal development**: chronic active inflammation, malabsorption, malnutrition and long-term glucocorticoids contribute to short stature and delayed development, with physical and psychological consequences.
- **Metabolic bone disease**: more common with chronic disease beginning in childhood, resulting from chronic inflammation, dietary deficiency and malabsorption of calcium and vitamin D.
- **Drug side-effects and adherence issues**: young people are more likely to require azathioprine or biological therapy than adults. Poor adherence to therapy is more common than with adults, as younger patients may feel well, lack self-motivation to adhere and believe that drugs are ineffective or cause side-effects.
- **Loss of time from education**: physical illness, surgery, fatigue in chronic inflammatory bowel disease, privacy and dignity issues, and social isolation may all contribute.
- **Emotional difficulties**: may result from challenges in coping with illness, problems with forming interpersonal relationships, and issues relating to body image or sexual function.
Conclusions are best when pregnancy is carefully planned and disease is in remission. Methotrexate must be stopped 3 months prior to conception; other IBD drugs should be continued until discussed with a specialist. Aminosalicylates and azathioprine are safe in pregnancy. Glucocorticoids are probably safe. Anti-tumour necrosis factor biological therapy in pregnancy can continue if established pregnancy but should be withheld in the third trimester due to placental transfer of antibody. No data are available for the use of vedolizumab in pregnancy. Daily high-dose (≥2 mg) folic acid supplements are recommended.

Pregnancy
- Two-thirds of patients in remission will remain so in pregnancy.
- Active disease is likely to remain active.
- Severe active disease carries an increased risk of premature delivery and low birth weight.
- Gentle flexible sigmoidoscopy is safe after the first trimester.
- X-rays can be performed if clinically indicated but discuss with the radiologist first.
- Colonoscopy can be performed safely if the potential benefits outweigh the risks.

Breastfeeding
- This is safe and does not exacerbate IBD.
- Data on the risk to babies from drugs excreted in breast milk are limited; most of these drugs are probably safe.
- Patients should discuss breastfeeding and drug therapy with their doctor.

Metabolic bone disease
Patients with IBD are prone to developing osteoporosis due to the effects of chronic inflammation, glucocorticoids, weight loss, malnutrition, and malabsorption. Osteomalacia can also occur in Crohn’s disease that is complicated by malabsorption, but is less common than osteoporosis. The risk of osteoporosis increases with age and with the dose and duration of glucocorticoid therapy.

Irritable bowel syndrome
Irritable bowel syndrome (IBS) is characterised by recurrent abdominal pain in association with abnormal defecation in the absence of a structural abnormality of the gut. About 10–15% of the population are affected at some time but only 10% of these consult their doctors because of symptoms. Nevertheless, IBS is the most common cause of gastrointestinal referral and accounts for frequent absenteeism from work and impaired quality of life. Young women are affected 2–3 times more often than men. Coexisting conditions, such as non-ulcer dyspepsia, chronic fatigue syndrome, dysmenorrhoea and fibromyalgia, are common. IBS is sometimes associated with a history of physical or sexual abuse and this is an important aspect of the history as these patients benefit from psychologically based therapy.

Pathophysiology
The cause of IBS is incompletely understood but biopsychosocial factors are thought to play an important role, along with luminal factors, such as diet and the gut microbiota, as discussed below.

Behavioural and psychosocial factors
Most patients seen in general practice do not have psychological problems but about 50% of patients referred to hospital have a psychiatric illness, such as anxiety, depression, somatisation and neurosis. Panic attacks are also common. Acute psychological stress and overt psychiatric disease are known to alter visceral perception and gastrointestinal motility. There is an increased prevalence of abnormal illness behaviour, with frequent consultations for minor symptoms and reduced coping ability (p. 1202). These factors contribute to but do not cause IBS.

Physiological factors
There is some evidence that IBS may be a serotoninergic (5-HT) disorder, as evidenced by relatively excessive release of 5-HT in diarrhoea-predominant IBS (D-IBS) and relative deficiency with constipation-predominant IBS (C-IBS). Accordingly, 5-HT3 receptor antagonists are effective in D-IBS, while 5-HT4 agonists improve bowel function in C-IBS. There is some evidence that IBS may represent a state of low-grade gut inflammation or immune activation, not detectable by tests, with raised numbers of mucosal mast cells that sensitise enteric neurons by releasing histamine and tryptase. Some patients respond positively to mast cell stabilisers, such as ketotifen, which supports a pathogenic role of mast cells in at least some patients. Immune activation may be associated with altered CNS processing of visceral pain signals. This is more common in women and in D-IBS, and may be triggered by a prior episode of gastroenteritis with Salmonella or Campylobacter species.
Luminal factors

Both quantitative and qualitative alterations in intestinal bacterial microbiota have been reported. Small intestinal bacterial overgrowth (SIBO) may be present in some patients and lead to symptoms. This ‘gut dysbiosis’ may explain the response to probiotics or the non-absorbable antibiotic rifaximin.

Dietary factors are also important. Some patients have chemical food intolerances (not allergy) to poorly absorbed, short-chain carbohydrates (lactose, fructose and sorbitol, among others), collectively known as FODMAPs (fermentable oligo-, di- and monosaccharides, and polyols). Their fermentation in the colon leads to bloating, pain, wind and altered bowel habit. Non-coeliac gluten sensitivity (negative coeliac serology and normal duodenal biopsies) seems to be present in some IBS patients, while others may be intolerant of chemicals such as salicylates or benzoates, found in certain foods.

Clinical features

The most common presentation is that of recurrent abdominal discomfort (Box 21.63). This is usually colicky or cramping in nature, felt in the lower abdomen and relieved by defecation. Abdominal bloating worsens throughout the day; the cause is unknown but it is not due to excessive intestinal gas. The bowel habit is variable. Most patients alternate between episodes of diarrhoea and constipation but it is useful to classify them as having predominantly constipation or predominantly diarrhoea. Those with constipation tend to pass infrequent pellet stools, usually in association with abdominal pain or proctalgia. Those with diarrhoea have frequent defecation but produce low-volume stools and rarely have nocturnal symptoms. Passage of mucus is common but rectal bleeding does not occur. Patients do not lose weight and are constitutionally well. Physical examination is generally unremarkable, with the exception of variable tenderness to palpation.

Investigations

The diagnosis is clinical in nature and can be made confidently in most patients using the Rome criteria combined with the absence of alarm symptoms, without resorting to complicated tests (Box 21.64). Full blood count and faecal calprotectin, with or without sigmoidoscopy, are usually done and are normal in IBS. Colonoscopy should be undertaken in older patients (over 40 years of age) to exclude colorectal cancer. Endoscopic examination is also required in patients who report rectal bleeding to exclude colon cancer and IBD. Those who present atypically require investigations to exclude other gastrointestinal diseases. Diarrhoea-predominant patients justify investigations to exclude coeliac disease (p. 805), microscopic colitis (p. 824), lactose intolerance (p. 812), bile acid diarrhoea (p. 809), thyrotoxicosis (p. 635) and, in developing countries, parasitic infection.

Management

The most important steps are to make a positive diagnosis and reassure the patient. Many people are concerned that they have developed cancer. A cycle of anxiety leading to colonic symptoms, which further heighten anxiety, can be broken by explaining that symptoms are not due to a serious underlying disease but instead are the result of behavioural, psychosocial, physiological and luminal factors. In individuals who fail to respond to reassurance, treatment is traditionally tailored to the predominant symptoms (Fig. 21.54). Dietary management is effective for many patients (Box 21.65).

Up to 20% may benefit from a wheat-free diet, some may respond to lactose exclusion, and excess intake of caffeine or artificial sweeteners, such as sorbitol, should be addressed. A more restrictive, ‘low-FODMAP’ diet, supervised by a dietitian, with gradual re-introduction of different food groups, may help some patients, as may a trial of a gluten-free diet. Probiotics, in capsule form, can be effective if taken for several months, although the optimum combination of bacterial strains and dose have yet to be clarified.

Patients with intractable symptoms sometimes benefit from several months of therapy with a tricyclic antidepressant, such as amitriptyline or imipramine (10–25 mg orally at night). Side-effects include dry mouth and drowsiness but these are usually mild and the drug is generally well tolerated, although patients with features of somatisation tolerate the drug poorly and lower doses should be used. It may act by reducing visceral sensation and by altering gastrointestinal motility. Anxiety and affective disorders may also require specific treatment (pp. 1200 and 1198). The 5-HT_{4} agonist prucalopride, the guanylate cyclase-C receptor agonist linaclotide, and chloride channel activators, such as lubiprostone, can be effective in constipation-predominant IBS.

Trials of anti-inflammatory agents, such as ketotifen or mesalazine, and the antibiotic rifaximin may be considered in

### 21.63 Rome III criteria for diagnosis of irritable bowel syndrome

- Recurrent abdominal pain or discomfort on at least 3 days per month in the last 3 months, associated with two or more of the following:
  - Improvement with defecation
  - Onset associated with a change in frequency of stool
  - Onset associated with a change in form (appearance) of stool

### 21.64 Supporting diagnostic features and alarm features in irritable bowel syndrome

#### Features supporting a diagnosis of IBS

- Presence of symptoms for more than 6 months
- Frequent consultations for non-gastrointestinal problems
- Previous medically unexplained symptoms
- Worsening of symptoms by stress

#### Alarm features

- Age >50 years; male gender
- Weight loss
- Nocturnal symptoms
- Family history of colon cancer
- Anaemia
- Rectal bleeding

(FODMAPs = fermentable oligo-, di- and monosaccharides, and polyols)
Psychological interventions, such as cognitive behavioural therapy, relaxation and gut-directed hypnotherapy, should be reserved for the most difficult cases. A range of complementary and alternative therapies exist; most lack a good evidence base but are popular and help some patients (Box 21.66).

Most patients have a relapsing and remitting course. Exacerbations often follow stressful life events, occupational dissatisfaction and difficulties with interpersonal relationships.

HIV/AIDS and the gastrointestinal tract

Patients with HIV/AIDS may develop several symptoms referable to the gastrointestinal tract, as discussed in detail on page 316. HIV testing should be considered in all patients with atypical or unexplained gastrointestinal symptoms and in those resident in areas of high prevalence.
Ischaemic gut injury is usually the result of arterial occlusion. Severe hypotension and venous insufficiency are less frequent causes. The presentation is variable, depending on the different vessels involved and the acuteness of the event. Diagnosis is often difficult.

**Acute small bowel ischaemia**

An embolus from the heart or aorta to the superior mesenteric artery is responsible for 40–50% of cases, thrombosis of underlying atheromatous disease for approximately 25%, and non-occlusive ischaemia due to hypotension complicating myocardial infarction, heart failure, arrhythmias or sudden blood loss for approximately 25%. Vasculitis and venous occlusion are rare causes. The clinical spectrum ranges from transient alteration of bowel function to transmural haemorrhagic necrosis and gangrene. Patients usually have evidence of cardiac disease and arrhythmia. Almost all develop abdominal pain that is more impressive than the physical findings. In the early stages, the only physical signs may be a silent, distended abdomen or diminished bowel sounds, with peritonitis developing only later.

Leucocytosis, metabolic acidosis, hyperphosphataemia and hyperamylasaemia are typical. Plain abdominal X-rays show “thumb-printing” due to mucosal oedema. Mesenteric or CT angiography reveals an occluded or narrowed major artery with spasm of arterial arcades, although most patients undergo laparotomy on the basis of a clinical diagnosis without angiography. Resuscitation, management of cardiac disease and intravenous antibiotic therapy, followed by laparotomy, are key steps. If treatment is instituted early, embolectomy and vascular reconstruction may salvage some small bowel. In these rare cases, a ‘second look’ laparotomy should be undertaken 24 hours later and further necrotic bowel resected.

In patients at high surgical risk, thrombolysis may sometimes be effective. The results of therapy depend on early intervention; patients treated late have a 75% mortality rate. Survivors often have nutritional failure from short bowel syndrome (p. 708) and require intensive nutritional support, including home parenteral nutrition and anticoagulation. Small bowel transplantation can be considered in selected patients. Patients with mesenteric venous thrombosis also require surgery if there are signs of peritonitis but are otherwise treated with anticoagulation. Investigations for underlying prothrombotic disorders should be performed (p. 978).

**Acute colonic ischaemia**

The splenic flexure and descending colon have little collateral circulation and lie in ‘watershed’ areas of arterial supply. The spectrum of injury ranges from reversible colopathy to transient colitis, colonic stricture, gangrene and fulminant pancolitis. Arterial thromboembolism is usually responsible but colonic ischaemia can also follow severe hypotension, colonic volvulus, strangulated hernia, systemic vasculitis or hypercoagulable states. Ischaemia of the descending and sigmoid colon is also a complication of abdominal aortic aneurysm surgery (where the inferior mesenteric artery is ligated). The patient is usually elderly and presents with sudden onset of cramping, left-sided, lower abdominal pain and rectal bleeding. Symptoms usually resolve spontaneously over 24–48 hours and healing occurs in 2 weeks. Some may develop a fibrous stricture or segment of colitis. A minority develop gangrene and peritonitis. The diagnosis is established by colonoscopy within 48 hours of presentation; otherwise, mucosal ulceration may have resolved. Resection is required for peritonitis.

**Chronic mesenteric ischaemia**

This results from atherosclerotic stenosis of the coeliac axis, superior mesenteric artery and inferior mesenteric artery. At least two of the three vessels must be affected for symptoms to develop. The typical presentation is with dull but severe mid- or upper abdominal pain developing about 30 minutes after eating. Weight loss is common because patients are reluctant to eat and some experience diarrhoea. Physical examination shows evidence of generalised arterial disease. An abdominal bruit is sometimes audible but is non-specific. The diagnosis is made by mesenteric angiography. Treatment is by vascular reconstruction or percutaneous angioplasty, if the patient’s clinical condition permits. The condition is frequently complicated by intestinal infarction, if left untreated.

**Disorders of the colon and rectum**

**Tumours of the colon and rectum**

**Polyps and polyposis syndromes**

Polyps may be neoplastic or non-neoplastic. The latter include hamartomas, metastatic (‘hyperplastic’) polyps and inflammatory polyps. These have no malignant potential. Polyps may be single or multiple and vary from a few millimetres to several centimetres in size.

Colorectal adenomas are extremely common in the Western world and the prevalence rises with age; 50% of people over 60 years of age have adenomas, and in half of these the polyps are multiple. They are more common in the rectum and distal colon and are either pedunculated or sessile. Histologically, they are classified as either tubular, villous or tubulovillous, according to the glandular architecture. Nearly all forms of colorectal carcinoma develop from adenomatous polyps, although not all polyps carry the same degree of risk. Features associated with a higher risk of subsequent malignancy are listed in Box 21.67.

Adenomas are usually asymptomatic and discovered incidentally. Occasionally, they cause bleeding and anaemia. Villous adenomas can secrete large amounts of mucus, causing diarrhoea and hypokalaemia.

Discovery of a polyp at sigmoidoscopy is an indication for colonoscopy because proximal polyps are present in 40–50% of such patients. Colonoscopic polypectomy should be carried out wherever possible, as this considerably reduces subsequent colorectal cancer risk (Fig. 21.55). Very large or sessile polyps can sometimes be removed safely by endoscopic mucosal resection (EMR) but many require surgery. Once all polyps have been removed, surveillance colonoscopy should be undertaken at 3–5-year intervals, as new polyps develop in 50% of patients. Patients over 75 years of age do not require repeated colonoscopies, as their subsequent lifetime cancer risk is low.

**21.67 Risk factors for malignant change in colonic polyps**

- Large size (>2 cm)
- Multiple polyps
- Villous architecture
- High-grade dysplasia
accounting for 1% of all colorectal cancers. It results from germline mutation of the tumour suppressor \( \text{APC} \) gene, followed by acquired mutation of the remaining allele (Ch. 3). The \( \text{APC} \) gene is large and over 1400 different mutations have been reported, but most are loss-of-function mutations resulting in a truncated \( \text{APC} \) protein. This protein normally binds to and sequesters \( \beta \)-catenin but is unable to do so when mutated, allowing \( \beta \)-catenin to translocate to the nucleus, where it up-regulates the expression of many genes.

Around 20% of cases arise as new mutations and have no family history. Hundreds to thousands of adenomatous colonic polyps develop in 80% of patients by age 15 (Fig. 21.56), with symptoms such as rectal bleeding beginning a few years later. In those affected, cancer will develop within 10–15 years of the appearance of adenomas and 90% of patients will develop colorectal cancer by the age of 50 years. Despite surveillance, approximately 1 in 4 patients with FAP have cancer by the time they undergo colectomy.

### 21.68 Gastrointestinal polyposis syndromes

</tr>
</tbody>
</table>

Between 10% and 20% of polyps show histological evidence of malignancy. When cancer cells are found within 2 mm of the resection margin of the polyp, when the polyp cancer is poorly differentiated or when lymphatic invasion is present, segmental colonic resection is recommended because residual tumour or lymphatic spread (in up to 10%) may be present. Malignant polyps without these features can be followed up by surveillance colonoscopy.

Polyposis syndromes are classified by histopathology (Box 21.68). It is important to note that, while the hamartomatous polyps in Peutz–Jeghers syndrome and juvenile polyposis are not themselves neoplastic, these disorders are associated with an increased risk of malignancy of the breast, colon, ovary and thyroid.

**Familial adenomatous polyposis**

Familial adenomatous polyposis (FAP) is an uncommon autosomal dominant disorder affecting 1 in 13 000 of the population and accounting for 1% of all colorectal cancers. It results from germline mutation of the tumour suppressor \( \text{APC} \) gene, followed by acquired mutation of the remaining allele (Ch. 3). The \( \text{APC} \) gene is large and over 1400 different mutations have been reported, but most are loss-of-function mutations resulting in a truncated \( \text{APC} \) protein. This protein normally binds to and sequesters \( \beta \)-catenin but is unable to do so when mutated, allowing \( \beta \)-catenin to translocate to the nucleus, where it up-regulates the expression of many genes.

Around 20% of cases arise as new mutations and have no family history. Hundreds to thousands of adenomatous colonic polyps develop in 80% of patients by age 15 (Fig. 21.56), with symptoms such as rectal bleeding beginning a few years later. In those affected, cancer will develop within 10–15 years of the appearance of adenomas and 90% of patients will develop colorectal cancer by the age of 50 years. Despite surveillance, approximately 1 in 4 patients with FAP have cancer by the time they undergo colectomy.
Disorders of the colon and rectum

Peutz–Jeghers syndrome

Multiple hamartomatous polyps occur in the small intestine and colon, as well as melanin pigmentation of the lips, mouth and digits (Fig. 21.57). Most cases are asymptomatic, although chronic bleeding, anaemia or intussusception can occur. There is a significant risk of small bowel or colonic adenocarcinoma and of cancer of the pancreas, lung, testis, ovary, breast and endometrium. Peutz–Jeghers syndrome is an autosomal dominant disorder, most commonly resulting from truncating mutations in a serine–threonine kinase gene on chromosome 19p (STK11).

Diagnosis requires two of the following features:
- small bowel polyposis
- mucocutaneous pigmentation
- a family history suggesting autosomal dominant inheritance.

The diagnosis can be made by genetic testing but this may be inconclusive, since mutations in genes other than STK11 can cause the disorder. Affected people should undergo regular upper endoscopy, colonoscopy and small bowel and pancreatic imaging. Polyps greater than 1 cm in size should be removed. Testicular examination is essential for men, while women should undergo pelvic examination, cervical smears and regular mammography. Asymptomatic relatives of affected patients should also undergo screening.

Juvenile polyposis

In juvenile polyposis, tens to hundreds of mucus-filled hamartomatous polyps are found in the colorectum. One-third of cases are inherited in an autosomal dominant manner and up to one-fifth develop colorectal cancer before the age of 40. The criteria for diagnosis are:
- ten or more colonic juvenile polyps
- juvenile polyposis elsewhere in the gut, or
- any polyps in those with a family history.

Germline mutations in the SMAD4 gene are often found, as are PTEN mutations. Colonoscopy with polypectomy should be performed every 1–3 years and colectomy considered for extensive involvement.
Colorectal cancer

Although relatively rare in the developing world, colorectal cancer is the second most common malignancy and the second leading cause of cancer deaths in Western countries. In the UK, the incidence is 50–60 per 100,000, equating to 30,000 cases per year. The condition becomes increasingly common over the age of 50 years.

Pathophysiology

Both environmental and genetic factors are important in colorectal carcinogenesis (Fig. 21.58). Environmental factors account for the wide geographical variation in incidence and the decrease in risk seen in migrants who move from high- to low-risk countries. Dietary factors are most important and these are summarised in Box 21.70; other recognised risk factors are listed in Box 21.71.

Colorectal cancer development results from the accumulation of multiple genetic mutations. There are also associated epigenetic influences, such as microRNA expression signature, and potential influences from non-coding genetic variation. Currently, there are three main pathways of genetic instability and each is associated with histological, clinical and prognostic parameters:

- **Chromosomal instability.** Mutations or deletions of portions of chromosomes arise, with loss of heterozygosity (LOH) and inactivation of specific tumour suppressor genes. In LOH, one allele of a gene is deleted but gene inactivation occurs only when a subsequent unrelated mutation affects the other allele. Chromosomal instability (CIN) occurs in around 85% of colorectal cancers. Figure 21.59 outlines some of the common genes affected by CIN.
- **Microsatellite instability.** This involves germline mutations in one of six genes encoding enzymes involved in repairing errors that occur normally during DNA replication (DNA mismatch repair); these genes are designated hMSH2, hMSH6, hMLH1, hMLH3, hPMS1 and hPMS2. Replication errors accumulate and can be detected in ‘microsatellites’ of repetitive DNA sequences. They also occur in important regulatory genes, resulting in a genetically unstable phenotype and accumulation of multiple somatic mutations throughout the genome that eventually lead to cancer. Around 15% of sporadic cancers develop this way, as do most cases of hereditary non-polyposis colon cancer (hHNPPCC).
- **CpG island methylator phenotype (CIMP).** This phenotype is found in approximately 20–30% of colorectal cancers and results in widespread gene hypermethylation. The result is functional loss of tumour suppressor genes.

**Pathogenesis of CRC**

*Evidence is inconsistent and a clear relationship is unproven.

**21.71 Non-dietary risk factors for colorectal cancer**

**Medical conditions**

- Colorectal adenomas (p. 827)
- Long-standing extensive ulcerative colitis or Crohn’s colitis (p. 813), especially if associated with primary sclerosing cholangitis
- Ureterosigmoidostomy
- Acromegaly
- Pelvic radiotherapy

**Others**

- Obesity and sedentary lifestyle – may be related to diet
- Smoking (relative risk 1.5–3.0)
- Alcohol (weak association)
- Cholecystectomy (effect of bile acids in right colon)
- Type 2 diabetes (hyperinsulinaemia)
- Use of aspirin or NSAIDs (COX-2 inhibition) and perhaps statins associated with reduced risk

(COX-2 = cyclo-oxygenase 2; NSAIDs = non-steroidal anti-inflammatory drugs)
The diagnostic criteria are listed in Box 21.72. In a subset of sporadic colon cancer, two-thirds of tumours occur proximally, with a mean age at cancer development of 45 years. In contrast at a young age. The lifetime risk in affected individuals is 80%, inheritance and a positive family history of colon cancer occurring. Pedigrees with this disorder have an autosomal dominant mode of heterogeneity resulting from both common and rare genetic variants, all displaying differing levels of penetrance.

With the advent of sophisticated sequencing methodologies, such as whole-exome or whole-genome sequencing, it is becoming clear that colorectal cancer displays molecular heterogeneity resulting from both common and rare genetic variants, all displaying differing levels of penetrance.

About 5–10% of colon cancers are caused by HNPCC. Pedigrees with this disorder have an autosomal dominant mode of inheritance and a positive family history of colon cancer occurring at a young age. The lifetime risk in affected individuals is 80%, with a mean age at cancer development of 45 years. In contrast to sporadic colon cancer, two-thirds of tumours occur proximally. The diagnostic criteria are listed in Box 21.72. In a subset of patients, there is also an increased incidence of cancers of the endometrium, ovary, urinary tract, stomach, pancreas, small intestine and CNS, related to inheritance of different mismatch repair gene mutations. Those who fulfil the criteria for HNPCC should be referred for pedigree assessment, genetic testing (see above) and colonoscopy. These should begin around 25 years of age or 5–10 years earlier than the youngest case of cancer in the family. Colonoscopy needs to be repeated every 1–2 years but, even then, interval cancers can still occur.

A family history of colorectal cancer can be obtained in 20% of patients who do not fulfil the criteria for HNPCC. In these families, the lifetime risk of developing colon cancer is 1 in 12 and 1 in 6, respectively, when one or two first-degree relatives are affected. The risk is even higher if relatives were affected at an early age. The genes responsible for these cases are, however, unknown.

Most colorectal cancers are ‘sporadic’ and arise from malignant transformation of a benign adenomatous polyp. Over 65% occur in the rectosigmoid and a further 15% occur in the caecum or ascending colon. Synchronous tumours are present in 2–5% of patients. Spread occurs through the bowel wall. Rectal cancers may invade the pelvic viscera and side walls. Lymphatic invasion is common at presentation, as is spread through both portal and systemic circulations to reach the liver and, less commonly, the lungs. Tumour stage at diagnosis is the most important determinant of prognosis (Fig. 21.60).

### Clinical features

Symptoms vary, depending on the site of the carcinoma. In tumours of the left colon, fresh rectal bleeding is common and obstruction occurs early. Tumours of the right colon present with anaemia from occult bleeding or with altered bowel habit, but obstruction is a late feature. Colicky lower abdominal pain is present in two-thirds of patients and rectal bleeding occurs in 50%. A minority present with features of either obstruction or perforation, leading to peritonitis, localised abscess or fistula formation. Carcinoma of the rectum usually causes early bleeding, mucus discharge or a feeling of incomplete emptying. Between 10% and 20% of patients present with iron deficiency anaemia or weight loss. On examination, there may be a palpable mass, signs of anaemia or hepatomegaly from metastases. Low rectal tumours may be palpable on digital examination.

**Fig. 21.59** The multistep origin of cancer: molecular events implicated in colorectal carcinogenesis. (GTP = guanine triphosphate)
Most recurrences are within 3 years of diagnosis and affect the liver, lung, distant lymph nodes and peritoneum. Adjuvant chemotherapy with 5-fluorouracil/folinic acid or capecitabine, preferably in combination with oxaliplatin, can reduce the risk of recurrence in patients with Dukes stage C cancers and some high-risk Dukes B cancers. Post-operative radiotherapy reduces the risk of local recurrence in rectal cancer if operative resection margins are involved.

Palliation of advanced disease

Surgical resection of the primary tumour is appropriate for some patients with metastases to treat obstruction, bleeding or pain. Palliative chemotherapy with 5-fluorouracil/folinic acid, capecitabine, oxaliplatin or irinotecan improves survival. Patients with advanced metastatic disease may be treated with monoclonal antibodies using bevacizumab or cetuximab, either alone or together with chemotherapy. Pelvic radiotherapy is sometimes useful for distressing rectal symptoms, such as pain, bleeding or severe tenesmus. Endoscopic laser therapy or insertion of an expandable metal stent can be used to relieve obstruction (Fig. 21.61).

Prevention and screening

Secondary prevention aims to detect and remove lesions at an early or pre-malignant stage by screening the asymptomatic general population. Several potential methods exist:

- Population-based screening of people over the age of 50 years by regular faecal occult blood (FOB) testing reduces colorectal cancer mortality and increases the proportion of early cancers detected. The sensitivity and specificity of these tests need to be improved. Traditionally, serial stool testing with or without subsequent colonoscopy is the screening method of choice in the UK.
- Colonoscopy remains the gold standard and allows preventative polypectomy but is expensive, requires bowel preparation and carries risks (perforation approximately 1:1000). Many countries lack the resources to offer this form of screening.
- Flexible sigmoidoscopy is an alternative option and has been shown to reduce overall colorectal cancer mortality by approximately 35% (70% for cases arising in the proximal colon).
Disorders of the colon and rectum

IBD and infection. Diverticular disease may be complicated by perforation, pericolic abscess, fistula formation (usually colovesical) or acute rectal bleeding. These complications are more common in patients who take NSAIDs or aspirin. After one attack of diverticulitis, the recurrence rate is around 3% per year. Over 10–30 years, perforation, obstruction or bleeding may occur, each affecting 5% of patients.

**Diverticulosis**

Diverticula are acquired and are most common in the sigmoid and descending colon of middle-aged people. Asymptomatic diverticula (diverticulosis) are present in over 50% of people above the age of 70 years. Symptomatic diverticular disease supervenes in 10–25% of cases, while complicated diverticulosis (acute diverticulitis, pericolic abscess, bleeding, perforation or stricture) is uncommon.

**Pathophysiology**

A life-long refined diet with a relative deficiency of fibre is widely thought to be responsible and the condition is rare in populations with a high dietary fibre intake, such as in Asia, where it more often affects the right side of the colon. It is postulated that small-volume stools require high intracolonic pressures for propulsion and this leads to herniation of mucosa between the taeniae coli (Fig. 21.62). Diverticula consist of protrusions of mucosa covered by peritoneum. There is commonly hypertrophy of the circular muscle coat. Inflammation is thought to result from impaction of diverticula with faecoliths. This may resolve spontaneously or progress to cause haemorrhage, perforation, local abscess formation, fistula and peritonitis. Repeated attacks of inflammation lead to thickening of the bowel wall, narrowing of the lumen and eventual obstruction.

**Clinical features**

Symptoms are usually the result of associated constipation or spasm. Colicky pain is suprapubic or felt in the left iliac fossa. The sigmoid colon may be palpable and, in attacks of diverticulitis, there is local tenderness, guarding, rigidity ('left-sided appendicitis') and sometimes a palpable mass. During these episodes, there may be diarrhea, rectal bleeding or fever. The differential diagnosis includes colorectal cancer, ischaemic colitis, and IBD.

**Investigations**

Investigations are usually performed to exclude colorectal neoplasia. Diverticula can be seen during colonoscopy or on imaging modalities such as CT scan, CT colonography or barium enema (see Fig. 21.12C, p. 773). In severe diverticulosis, colonoscopy requires expertise and carries a risk of perforation. CT is used to assess complications, such as perforation or pericolic abscess.
Management

Diverticular disease that is asymptomatic and discovered coincidentally requires no treatment. Constipation can be relieved by a high-fibre diet, with or without a bulking laxative (ispaghula husk, 1–2 sachets daily), taken with plenty of fluids. Stimulant laxatives (see Box 21.73 below) should be avoided. Antispasmodics may sometimes help. Acute attacks of diverticulitis can be treated with antibiotics active against Gram-negative and anaerobic organisms. Severe cases require intravenous fluids, intravenous antibiotics, analgesia and nasogastric suction, but randomised trials show no benefit from acute resection compared to conservative management. Emergency surgery is reserved for severe haemorrhage or perforation. Percutaneous drainage of acute paracolic abscesses can be effective and avoids the need for emergency surgery. Patients who have repeated attacks of obstruction should undergo elective surgery once the acute episode has settled, in order to resect the affected segment of bowel with restoration of continuity by primary anastomosis.

**Constipation and disorders of defecation**

The clinical approach to patients with constipation and its aetiology have been described on page 786.

**Simple constipation**

Simple constipation is extremely common and does not signify underlying organic disease. It usually responds to increased dietary fibre or the use of bulking agents; an adequate fluid intake is also essential. Many types of laxative are available, and these are listed in Box 21.73.

**Severe idiopathic constipation**

This occurs almost exclusively in young women and often begins in childhood or adolescence. The cause is unknown but some have ‘slow transit’ with reduced motor activity in the colon. Others have ‘obstructed defecation’, resulting from inappropriate contraction of the external anal sphincter and puborectalis muscle (anismus). The condition is often resistant to treatment. Bulking agents may exacerbate symptoms but prokinetic agents or (anismus). The condition is often resistant to treatment. Bulking agents may exacerbate symptoms but prokinetic agents or

*Also used for bowel preparation prior to investigation or surgery.

---

### 21.74 Constipation in old age

- **Evaluation**: particular attention should be paid to immobility, dietary fluid and fibre intake, drugs and depression.
- **Immobility**: predisposes to constipation by increasing the colonic transit time; the longer this is, the greater the fluid absorption and the harder the stool.
- **Bulking agents**: can make matters worse in patients with slow transit times and should be avoided.
- **Overflow diarrhoea**: if faecal impaction develops, paradoxical overflow diarrhoea may occur. If antidiarrhoeal agents are given, the underlying impaction may worsen and result in serious complications, such as stercoral ulceration and bleeding.

---

### Faecal impaction

In faecal impaction, a large, hard mass of stool fills the rectum. This tends to occur in disabled, immobile or institutionalised patients, especially the frail elderly or those with dementia. Constipating drugs, autonomic neuropathy and painful anal conditions also contribute. Megacolon, intestinal obstruction and urinary tract infections may supervene. Perforation and bleeding from pressure-induced ulceration are occasionally seen. Treatment involves adequate hydration and careful digital disimpaction after softening the impacted stool with arachis oil enemas. Stimulants should be avoided.

### Melanosis coli and laxative misuse syndromes

Long-term consumption of stimulant laxatives leads to accumulation of lipofuscin pigment in macrophages in the lamina propria. This imparts a brown discoloration to the colonic mucosa, often described as resembling ‘tiger skin’. The condition is benign and resolves when the laxatives are stopped. Prolonged laxative use may rarely result in megacolon or ‘catarrh colon’, in which barium enema demonstrates a featureless mucosa, loss of haustra and shortening of the bowel. Suppurative laxative misuse is a psychiatric condition seen in young women, some of whom have a history of bulimia or anorexia nervosa (pp. 1203 and 1204). They complain of refractory watery diarrhoea. Laxative use is usually denied and may continue, even when patients are undergoing investigation. Screening of urine for laxatives may reveal the diagnosis.

### Hirschsprung’s disease

This disease is characterised by constipation and colonic dilatation (megacolon) due to congenital absence of ganglion cells in the large intestine. The incidence is approximately 1:5000. About one-third of patients have a positive family history and, in these families, the disease is inherited in an autosomal dominant manner with incomplete penetrance. About 50% of familial cases and 15% of sporadic cases have mutations affecting the RET proto-oncogene, which is also implicated in multiple endocrine neoplasia (MEN) types 2 and 3 (also known as MEN 2a and 2b, respectively; p. 688). Unlike MEN 2 and 3, which are caused by activating RET mutations, Hirschsprung’s disease is caused by loss-of-function mutations. In some kindreds, Hirschsprung’s disease and MEN can actually co-segregate and this presumably represents both ‘switch off’ and ‘switch on’ of RET in different tissues. Although RET is the most important susceptibility gene, some patients with
normal or high-pitched, rather than absent. Left untreated, it are no features of mechanical obstruction. Bowel sounds are of painless, massive enlargement of the proximal colon; there empty on digital examination.

A plain abdominal X-ray or barium enema shows a small rectum and colonic dilatation above the narrowed segment. Full-thickness biopsies are required to demonstrate nerve plexuses and confirm the absence of ganglion cells. Histochemical stains for acetylcholinesterase are also used. Anorectal manometry demonstrates failure of the rectum to relax with balloon distension. Treatment involves resection of the affected segment.

## Acquired megacolon

This may develop in childhood as a result of voluntary withholding of stool during toilet training. In such cases, it presents after the first year of life and is distinguished from Hirschsprung’s disease by the urge to defecate and the presence of stool in the rectum. It usually responds to osmotic laxatives.

In adults, acquired megacolon has several causes. It is seen in patients with depression or dementia, either as part of the condition or as a side-effect of antidepressant drugs. Prolonged misuse of stimulant laxatives may cause degeneration of the myenteric plexus, while interruption of sensory or motor innervation may be responsible in a number of neurological disorders. Patients taking large doses of opioid analgesics can develop a megacolon: so-called ‘narcotic bowel syndrome’. Systemic sclerosis and hypothyroidism are other recognised causes.

Most patients can be managed conservatively by treatment of the underlying cause, high-residue diets, laxatives and the judicious use of enemas. Prokinetics are helpful in a minority of patients. Opioid-associated constipation can be treated with the specific peripheral opioid receptor antagonist naloxegol. Subtotal colectomy is a last resort for the most severely affected patients.

## Acute colonic pseudo-obstruction

Acute colonic pseudo-obstruction (Ogilvie’s syndrome) has many causes (Box 21.75) and is characterised by sudden onset of painless, massive enlargement of the proximal colon; there are no features of mechanical obstruction. Bowel sounds are normal or high-pitched, rather than absent. Left untreated, it may progress to perforation, peritonitis and death.

Abdominal X-rays show colonic dilatation with air extending to the rectum. Caecal diameter greater than 10 cm is associated with a high risk of perforation. Single-contrast or water-soluble barium enemas demonstrate the absence of mechanical obstruction.

Management consists of treating the underlying disorder and correcting any biochemical abnormalities. The anticholinesterase neostigmine is effective in enhancing parasympathetic activity and gut motility. Decompression, with either a rectal tube or colonoscope, may be effective but needs to be repeated until the condition resolves. In severe cases, surgical or fluoroscopic defunctioning caecostomy is necessary.

### Anorectal disorders

#### Faecal incontinence

The normal control of anal continence is described on page 770. Common causes of incontinence are listed in Box 21.76. High-risk patients include frail older people, women after childbirth and those with severe neurological/spinal disorders, learning difficulties or cognitive impairment.

Patients are often embarrassed to admit incontinence and may complain only of ‘diarrhoea’. A careful history and examination, especially of the anorectum and perineum, may help to establish the underlying cause. Endoanal ultrasound is valuable for defining the integrity of the anal sphincters, while anorectal physiology and MR proctography are also useful investigations.

#### Management

This is often very difficult. Underlying disorders should be treated and diarrhoea managed with loperamide, diphenoxylate or codeine phosphate. Attention must be paid to a proper diet and adequate fluid intake. Pelvic floor exercises, biofeedback and bowel retraining techniques help some patients, and those with confirmed anal sphincter defects may benefit from sphincter repair operations. Where sphincter repair is not appropriate, a trial of sacral nerve stimulation is undertaken with a view to insertion of a permanent stimulator but, if unsuccessful, creation of a neo-sphincter may be possible, by graciloplasty or by an artificial anal sphincter.

#### Haemorrhoids

Haemorrhoids (commonly known as piles) arise from congestion of the internal and/or external venous plexuses around the anal canal. They are extremely common in adults. The aetiology is unknown, although they are associated with constipation and straining, and may develop for the first time during pregnancy. First-degree piles bleed, while second-degree piles prolapse but retract spontaneously. Third-degree piles are those that require manual replacement after prolapsing. Bright red rectal bleeding occurs after defecation. Other symptoms include pain, pruritus ani and mucus discharge; thrombosis can occur in prolapsed piles, which can be very painful (Fig. 21.63). Treatment

### 21.75 Causes of acute colonic pseudo-obstruction

- Trauma, burns
- Recent surgery
- Drugs (opiates, phenothiazines)
- Respiratory failure
- Electrolyte and acid-base disorders
- Diabetes mellitus
- Uraemia

### 21.76 Causes of faecal incontinence

- Obstetric trauma: childbirth, hysterectomy
- Severe diarrhoea
- Faecal impaction
- Congenital anorectal anomalies
- Anorectal disease: haemorrhoids, rectal prolapse, Crohn’s disease
- Neurological disorders: spinal cord or cauda equina lesions, dementia
and mucosal prolapse. The ulcer is seen at sigmoidoscopy and biopsies show a characteristic accumulation of collagen.

Symptoms include minor bleeding and mucus per rectum, tenesmus and perineal pain. Treatment is often difficult but avoidance of straining at defecation is important and treatment of constipation may help. Marked mucosal prolapse is treated surgically.

### Anal fissure

In this common problem, traumatic or ischaemic damage to the anal mucosa results in a superficial mucosal tear, most commonly in the midline posteriorly. Spasm of the internal anal sphincter exacerbates the condition. Severe pain occurs on defecation and there may be minor bleeding, mucus discharge and pruritus. The skin may be indurated and an oedematous skin tag, or ‘sentinel pile’, adjacent to the fissure is common.

Avoidance of constipation with bulk-forming laxatives and increased fluid intake is important. Relaxation of the internal sphincter is normally mediated by nitric oxide, and 0.2% glyceryl trinitrate, which donates nitric oxide and improves mucosal blood flow, is effective in 60–80% of patients. Diltiazem cream (2%) can be used as an alternative. Resistant cases may respond to injection of botulinum toxin into the internal anal sphincter to induce relaxation. Manual dilatation under anaesthesia leads to long-term incontinence and should not be considered. The majority of cases can be treated without surgery, but where these measures fail, healing can be achieved surgically by lateral internal anal sphincterotomy or advancement anoplasty.

### Anorectal abscesses and fistulae

Perianal abscesses develop between the internal and external anal sphincters and may point at the perianal skin. Ischiorectal abscesses occur lateral to the sphincters in the ischiorectal fossa. They usually result from infection of anal glands by normal intestinal bacteria. Crohn’s disease (p. 813) is sometimes responsible. Patients complain of extreme perianal pain, fever and/or discharge of pus. Spontaneous rupture may lead to the development of fistulae. These may be superficial or track through the anal sphincters to reach the rectum. Abscesses are drained surgically and superficial fistulae are laid open with care to avoid sphincter damage.

### Diseases of the peritoneal cavity

#### Peritonitis

Surgical peritonitis occurs as the result of a ruptured viscus (for details see this book’s companion text, *Principles and Practice of Surgery*). Peritonitis may also complicate ascites in chronic liver disease (spontaneous bacterial peritonitis, p. 864) or may occur in children in the absence of ascites, due to infection with *Streptococcus pneumoniae* or β-haemolytic streptococci (p. 253).

Chlamydial peritonitis is a complication of pelvic inflammatory disease (p. 336). The patient presents with right upper quadrant pain, pyrexia and a hepatic rub (the Fitz–Hugh–Curtis syndrome). Tuberculosis may cause peritonitis and ascites (p. 588).

#### Tumours

The most common is secondary adenocarcinoma from the ovary or gastrointestinal tract. Mesothelioma is a rare tumour complicating asbestos exposure. It presents as a diffuse...
abdominal mass, due to omental infiltration, and with ascites. The prognosis is extremely poor.

Other disorders

Endometriosis

Ectopic endometrial tissue can become embedded on the serosal aspect of the intestine, most frequently in the sigmoid and rectum. The overlying mucosa is usually intact. Cyclical engorgement and inflammation result in pain, bleeding, diarrhoea, constipation and adhesions or obstruction. Low backache is frequent. The onset is usually between 20 and 45 years and the condition is more common in nulliparous women. Bimanual examination may reveal tender nodules in the pouch of Douglas. Endoscopic studies reveal the diagnosis only if carried out during menstruation, when a bluish mass with intact overlying mucosa is apparent. In some patients, laparoscopy is required. Treatment options include laparoscopic diathermy and hormonal therapy with progestogens (e.g. norethisterone), gonadotrophin-releasing hormone analogues or danazol.

Pneumatosis cystoides intestinalis

In this rare condition, multiple gas-filled submucosal cysts line the colonic and small bowel walls. The cause is unknown but the condition may be seen in patients with chronic cardiac or pulmonary disease, pyloric obstruction, systemic sclerosis or dermatomyositis. Most patients are asymptomatic, although there may be abdominal cramp, diarrhoea, tenesmus, rectal bleeding and mucus discharge. The cysts are recognised on sigmoidoscopy, plain abdominal X-rays or barium enema. Therapies reported to be effective include prolonged high-flow oxygen, elemental diets and antibiotics.

Diseases of the pancreas

Acute pancreatitis

Acute pancreatitis accounts for 3% of all cases of abdominal pain admitted to hospital. It affects 2–28 per 100 000 of the population and is increasing in incidence. It is a potentially serious condition with an overall mortality of 10%. About 80% of all cases are mild and have a favourable outcome. Approximately 98% of deaths from pancreatitis occur in the 20% of patients with severe disease and about one-third of these arise within the first week, usually from multi-organ failure. After this time, the majority of deaths result from sepsis, especially that complicating infected necrosis. At admission, it is possible to predict patients at risk of these complications (Box 21.78). Individuals who are predicted to have severe pancreatitis (Box 21.79) and those with necrosis or other complications should be managed in a specialist centre with an intensive care unit and multidisciplinary hepatobiliary specialists.

Pathophysiology

Acute pancreatitis occurs as a consequence of premature intracellular trypsinogen activation, releasing proteases that digest the pancreas and surrounding tissue. Triggers for this are many, including alcohol, gallstones and pancreatic duct obstruction (Fig. 21.64). There is simultaneous activation of nuclear factor kappa B (NFκB), leading to mitochondrial dysfunction, autophagy and a vigorous inflammatory response. The normal pancreas has only a poorly developed capsule, and adjacent structures, including the common bile duct, duodenum, splenic vein and transverse colon, are commonly involved in the inflammatory process. The severity of acute pancreatitis is dependent on the balance between the activity of released proteolytic enzymes and antiproteolytic factors. The latter comprise an intracellular pancreatic trypsin inhibitor protein and circulating α1-antitrypsin and C1-esterase inhibitors. The causes of acute pancreatitis are listed in Box 21.80. Acute pancreatitis is often self-limiting, but in some patients with severe disease, local complications, such as necrosis, pseudocyst or abscess, occur, as well as systemic complications that lead to multi-organ failure.

Clinical features

The typical presentation is with severe, constant upper abdominal pain, of increasing intensity over 15–60 minutes, which radiates to the back. Nausea and vomiting are common. There is marked epigastric tenderness, but in the early stages (and in contrast to a perforated peptic ulcer), guarding and rebound tenderness are absent because the inflammation is principally retroperitoneal. Bowel sounds become quiet or absent as paralytic ileus develops. In severe cases, the patient becomes hypoxic and develops hypovolaemic shock with oliguria. Discoloration of the flanks

### 21.78 Glasgow criteria for prognosis in acute pancreatitis

- Age > 55 years
- P02 < 8 kPa (60 mmHg)
- White blood cell count > 15 x 10^9/L
- Albumin < 32 g/L (3.2 g/dL)
- Serum calcium < 2 mmol/L (8 mg/dL) (corrected)
- Glucose > 10 mmol/L (180 mg/dL)
- Urea > 16 mmol/L (45 mg/dL) (after rehydration)
- Alanine aminotransferase > 200 U/L
- Lactate dehydrogenase > 600 U/L

*Severity and prognosis worsen as the number of these factors increases. More than three implies severe disease.*

### 21.79 Features that predict severe pancreatitis

#### Initial assessment

- Clinical impression of severity
- Body mass index > 30 kg/m²
- Pleural effusion on chest X-ray
- APACHE II score > 8 (see Box 10.50, p. 214)

#### 24 hours after admission

- Clinical impression of severity
- APACHE II score > 8
- Glasgow score > 3 (see Box 21.78)
- Persisting organ failure, especially if multiple
- CRP > 150 mg/L

#### 48 hours after admission

- Clinical impression of severity
- Glasgow score > 3
- CRP > 150 mg/L
- Persisting organ failure for 48 hours
- Multiple or progressive organ failure

(CRP = C-reactive protein)
‘pseudocysts’ are common and usually asymptomatic, resolving as the pancreatitis recovers. Pseudocysts greater than 6 cm in diameter seldom disappear spontaneously and can cause constant abdominal pain and compress or erode surrounding structures, including blood vessels, to form pseudoaneurysms. Large pseudocysts can be detected clinically as a palpable abdominal mass.

Pancreatic ascites occurs when fluid leaks from a disrupted pancreatic duct into the peritoneal cavity. Leakage into the thoracic cavity can result in a pleural effusion or a pleuro-pancreatic fistula.

(Grey Turner’s sign) or the periumbilical region (Cullen’s sign) is a feature of severe pancreatitis with haemorrhage. The differential diagnosis includes a perforated viscus, acute cholecystitis and myocardial infarction. Various complications may occur and these are listed in Box 21.81.

A collection of fluid and debris may develop in the lesser sac, following inflammatory rupture of the pancreatic duct; this is known as a pancreatic fluid collection. It is initially contained within a poorly defined, fragile wall of granulation tissue, which matures over a 6-week period to form a fibrous capsule (Fig. 21.65). Such...
Investigations

The diagnosis is based on raised serum amylase or lipase concentrations and ultrasound or CT evidence of pancreatic swelling. Plain X-rays should be taken to exclude other diagnoses, such as perforation or obstruction, and to identify pulmonary complications. Amylase is efficiently excreted by the kidneys and concentrations may have returned to normal if measured 24–48 hours after the onset of pancreatitis. A persistently elevated serum amylase concentration suggests pseudocyst formation. Peritoneal amylase concentrations are massively elevated in pancreatic ascites. Serum amylase concentrations are also elevated (but less so) in intestinal ischaemia, perforated peptic ulcer and ruptured ovarian cyst, while the salivary isoenzyme of amylase is elevated in parotitis. If available, serum lipase measurements are preferable to amylase, as they have greater diagnostic accuracy for acute pancreatitis.

Ultrasound scanning can confirm the diagnosis, although in the earlier stages the gland may not be grossly swollen. The ultrasound scan is also useful because it may show gallstones, biliary obstruction or pseudocyst formation.

Contrast-enhanced pancreatic CT performed 6–10 days after admission can be useful in assessing viability of the pancreas if persisting organ failure, sepsis or clinical deterioration is present, since these features may indicate that pancreatic necrosis has occurred. Necrotising pancreatitis is associated with decreased pancreatic enhancement on CT, following intravenous injection of contrast material. The presence of gas within necrotic material (Fig. 21.66) suggests infection and impending abscess formation, in which case percutaneous aspiration of amylase, as they have greater diagnostic accuracy for acute pancreatitis.

Certain investigations stratify the severity of acute pancreatitis and have important prognostic value at the time of presentation (see Boxes 21.78 and 21.79). In addition, serial assessment of CRP is a useful indicator of progress. A peak CRP of >210 mg/L in the first 4 days predicts severe acute pancreatitis with 80% accuracy. It is worth noting that the serum amylase concentration has no prognostic value.

Management

Management comprises several related steps:
- establishing the diagnosis and disease severity
- early resuscitation, according to whether the disease is mild or severe
- detection and treatment of complications
- treatment of the underlying cause.

Opiate analgesics should be given to treat pain and hypovolaemia should be corrected using normal saline or other crystalloids. All severe cases should be managed in a high-dependency or intensive care unit. A central venous line and urinary catheter should be inserted to monitor patients with shock. Oxygen should be given to hypoxic patients, and those who develop systemic inflammatory response syndrome (SIRS) may require ventilatory support. Hyperglycaemia should be corrected using insulin and hypocalcaemia by intravenous calcium injection.

Nasogastric aspiration is required only if paralytic ileus is present. Enteral feeding, if tolerated, should be started at an early stage in patients with severe pancreatitis because they are in a severely catabolic state and need nutritional support. Enteral feeding decreases endotoxaemia and so may reduce systemic complications. Nasogastric feeding is just as effective as feeding by the nasojejunal route. Prophylaxis of thromboembolism with subcutaneous low-molecular-weight heparin is also advisable. The use of prophylactic, broad-spectrum intravenous antibiotics to prevent infection of pancreatic necrosis is not indicated, but infected necrosis is treated with antibiotics that penetrate necrotic tissue, e.g. carbapenems or quinolones, and metronidazole.

Patients who present with cholangitis or jaundice in association with severe acute pancreatitis should undergo urgent ERCP to diagnose and treat choledocholithiasis. In less severe cases of gallstone pancreatitis, biliary imaging (using MRCP or EUS) can be carried out after the acute phase has resolved. If the liver function tests return to normal and ultrasound has not demonstrated a dilated biliary tree, laparoscopic cholecystectomy with an on-table cholangiogram is appropriate because any common bile duct stones have probably passed. When the operative cholangiogram detects residual common bile duct stones, these should be removed by laparoscopic exploration of the duct or by post-operative ERCP. Cholecystectomy should be undertaken within 2 weeks of resolution of pancreatitis – and preferably during the same admission – to prevent further potentially fatal attacks of pancreatitis. Patients with infected pancreatic necrosis or pancreatic abscess require urgent endoscopic drainage or minimally invasive retroperitoneal pancreatic (MIRP) necrosectomy to debride all cavities of necrotic material. Pancreatic pseudocysts can be treated by drainage into the stomach or duodenum. This is usually performed after an interval of at least 6 weeks, once a pseudocapsule has matured, by surgical or endoscopic cystogastrostomy.

Chronic pancreatitis

Chronic pancreatitis is a chronic inflammatory disease characterised by fibrosis and destruction of exocrine pancreatic tissue. Diabetes mellitus occurs in advanced cases because the islets of Langerhans are involved (p. 733).

Pathophysiology

Around 80% of cases in Western countries result from alcohol misuse. In southern India, severe chronic calcific pancreatitis

![Fig. 21.66 Pancreatic necrosis. Lack of vascular enhancement of the pancreas during contrast-enhanced computed tomography indicates necrosis (arrow). The presence of gas suggests that infection has occurred.](image-url)
occurs in non-alcoholics, possibly as a result of malnutrition, deficiency of trace elements and micronutrients, and cassava consumption. Other causes are listed in Box 21.82. The pathophysiology of chronic pancreatitis is shown in Figure 21.67.

**Clinical features**

Chronic pancreatitis predominantly affects middle-aged alcoholic men. Almost all present with abdominal pain. In 50%, this occurs as episodes of ‘acute pancreatitis’, although each attack results in a degree of permanent pancreatic damage. Relentless, slowly progressive chronic pain without acute exacerbations affects 35% of patients, while the remainder have no pain but present with diarrhoea. Pain is due to a combination of increased pressure within the pancreatic ducts and direct involvement of peripancreatic nerves by the inflammatory process. Pain may be relieved by leaning forwards or by drinking alcohol. Approximately one-fifth of patients chronically consume opiate analgesics. Weight loss is common and results from a combination of anorexia, avoidance of food because of post-prandial pain, malabsorption and/or diabetes. Steatorrhoea occurs when more than 90% of the exocrine tissue has been destroyed; protein malabsorption develops only in the most advanced cases. Overall, 30% of patients have (secondary) diabetes but this figure rises to 70% in those with chronic calcific pancreatitis. Physical examination reveals a thin, malnourished patient with epigastric tenderness. Skin pigmentation over the abdomen and back is common and results from chronic use of a hot water bottle (erythema ab igne). Many patients have features of other alcohol- and smoking-related diseases. Complications are listed in Box 21.83.

**Investigations**

Investigations (Box 21.84 and Fig. 21.68) are carried out to:
- make a diagnosis of chronic pancreatitis
- define pancreatic function
- demonstrate anatomical abnormalities prior to surgical intervention.

**Complications of chronic pancreatitis**

- Pseudocysts and pancreatic ascites, which occur in both acute and chronic pancreatitis
- Obstructive jaundice due to benign stricture of the common bile duct as it passes through the diseased pancreas
- Duodenal stenosis
- Portal or splenic vein thrombosis leading to segmental portal hypertension and gastric varices
- Peptic ulcer

**Pathophysiology of chronic pancreatitis**

Fig. 21.67. Alcohol and other risk factors may trigger acute pancreatitis through multiple mechanisms. The first (or ‘sentinel’) episode of acute pancreatitis initiates an inflammatory response involving T-helper (Th) cells. Ongoing exposure to alcohol drives further inflammation but this is modified by regulatory T cells (Treg) with subsequent fibrosis, via activation of pancreatic stellate cells. A cycle of inflammation and fibrosis ensues, with development of chronic pancreatitis. Alcohol is the most relevant risk factor, as it is involved at multiple steps.
Pain relief

A range of analgesic drugs, particularly NSAIDs, are valuable but the severe and unremitting nature of the pain often leads to opiate use with the risk of addiction. Analgesics, such as pregabalin and tricyclic antidepressants at a low dose, may be effective. Oral pancreatic enzyme supplements suppress pancreatic secretion and their regular use reduces analgesic consumption in some patients. Patients who are abstinent from alcohol and who have severe chronic pain that is resistant to conservative measures should be considered for surgical or endoscopic pancreatic therapy (Box 21.85). Coeliac plexus neurolysis sometimes produces long-lasting pain relief, although relapse occurs in the majority of cases. In some patients, MRCP does not show a surgically or endoscopically correctable abnormality and, in these individuals, the only surgical approach is total pancreatectomy. Unfortunately, even after this operation, some continue to experience pain. Moreover, the procedure causes diabetes, which may be difficult to control, with a high risk of hypoglycaemia (since both insulin and glucagon are absent) and significant morbidity and mortality.

Malabsorption

This is treated by dietary fat restriction (with supplementary medium-chain triglyceride therapy in malnourished patients) and oral pancreatic enzyme supplements. A PPI is added to optimise duodenal pH for pancreatic enzyme activity.

Management of complications

Surgical or endoscopic therapy may be necessary for the management of pseudocysts, pancreatic ascites, common bile duct or duodenal stricture and the consequences of portal hypertension. Many patients with chronic pancreatitis also require treatment for other alcohol- and smoking-related diseases and for the consequences of self-neglect and malnutrition.

Autoimmune pancreatitis

Autoimmune pancreatitis (AIP) is a form of chronic pancreatitis that can mimic cancer but which responds to glucocorticoids. It is characterised by abdominal pain, weight loss or obstructive jaundice, without acute attacks of pancreatitis. Blood tests reveal increased serum IgG or IgG4 and the presence of other autoantibodies. Imaging shows a diffusely enlarged pancreas, narrowing of the pancreatic duct and stricturing of the lower bile duct. AIP may occur alone or with other autoimmune disorders, such as Sjögren’s syndrome, primary sclerosing cholangitis or IBD. The response to glucocorticoids is usually excellent but some patients require azathioprine.
Congenital abnormalities affecting the pancreas

Pancreas divisum

This is due to failure of the primitive dorsal and ventral ducts to fuse during embryonic development of the pancreas. As a consequence, most of the pancreatic drainage occurs through the smaller accessory ampulla rather than through the major ampulla. The condition occurs in 7–10% of the normal population and is usually asymptomatic, but some patients develop acute pancreatitis, chronic pancreatitis or atypical abdominal pain.

Annular pancreas

In this congenital anomaly, the pancreas encircles the second/third part of the duodenum, leading to gastric outlet obstruction. Annular pancreas is associated with malrotation of the intestine, atresias and cardiac anomalies.

Cystic fibrosis

This disease is considered in detail on page 580. The major gastrointestinal manifestations are pancreatic insufficiency and meconium ileus. Peptic ulcer and hepatobiliary disease may also occur. In cystic fibrosis, pancreatic secretions are protein- and mucus-rich. The resultant viscous juice forms plugs that obstruct the pancreatic ductules, leading to progressive destruction of acinar cells. Steatorrhea is universal and the large-volume bulky stools predispose to rectal prolapse. Malnutrition is compounded by the metabolic demands of respiratory failure and by diabetes, which develops in 40% of patients by adolescence.

Nutritional counselling and supervision are important to ensure intake of high-energy foods, providing 120–150% of the recommended intake for normal subjects. Fats are an important calorie source and, despite the presence of steatorrhea, fat intake should not be restricted. Supplementary fat-soluble vitamins are also necessary. High-dose oral pancreatic enzymes are required, in doses sufficient to control steatorrhea and stool frequency. A PPI aids fat digestion by producing an optimal duodenal pH.

Meconium ileus

Mucus-rich plugs within intestinal contents can obstruct the small or large intestine of a newborn child. Meconium ileus is treated by the mucolytic agent N-acetylcysteine, given either orally, by Gastrografin enema or by gut lavage using polyethylene glycol. In resistant cases of meconium ileus, surgical resection may be necessary.

Tumours of the pancreas

Adenocarcinoma of the pancreas

Some 90% of pancreatic neoplasms are adenocarcinomas that arise from the pancreatic ducts. These tumours involve local structures and metastasise to regional lymph nodes at an early stage. Most patients have advanced disease at the time of presentation. Neuro-endocrine tumours also arise in the pancreas but tend to grow more slowly and have a better prognosis; these are discussed in detail on page 678. Pancreatic adenocarcinoma affects 10–15 per 100,000 in Western populations, rising to 100 per 100,000 in those over the age of 70. Men are affected twice as often as women. The disease is associated with increasing age, smoking and chronic pancreatitis. Between 5% and 10% of patients have a genetic predisposition: hereditary pancreatitis, HNPCC and familial atypical mole multiple melanoma syndrome (FAMMM). Overall survival is only 3–5%, with a median survival of 6–10 months for those with locally advanced disease and 3–5 months if metastases are present.

Clinical features

Many patients are asymptomatic until an advanced stage, when they present with central abdominal pain, weight loss and obstructive jaundice (Fig. 21.69). The pain results from invasion of the coeliac plexus and is characteristically incessant and gnawing. It often radiates from the upper abdomen through to the back and may be eased a little by bending forwards. Almost all patients lose weight and many are cachectic. Around 60% of tumours arise from the head of the pancreas, and involvement of the common bile duct results in the development of obstructive jaundice, often with severe pruritus. A few patients present with diarrhoea, vomiting from duodenal obstruction, diabetes mellitus, recurrent venous thrombosis, acute pancreatitis or depression. Physical examination reveals clear evidence of weight loss. An abdominal mass due to the tumour itself, a palpable gallbladder or hepatic metastasis is commonly found. A palpable gallbladder in a jaundiced patient is usually the consequence of distal biliary obstruction by a pancreatic cancer (Courvoisier’s sign).

Investigations

The diagnosis is usually made by ultrasound and contrast-enhanced CT (Fig. 21.70). Diagnosis in non-jaundiced patients is often delayed because presenting symptoms are relatively non-specific. Fit patients with small, localised tumours should undergo staging to define operability. EUS or laparoscopy with laparoscopic ultrasound will define tumour size, involvement of blood vessels and metastatic spread. In patients unsuitable for surgery because of advanced disease, frailty or comorbidity, EUS- or CT-guided cytology or biopsy can be used to confirm the diagnosis (Fig. 21.70). MRCP and ERCP are sensitive methods of diagnosing pancreatic cancer and are valuable when the diagnosis is in doubt, although differentiation between cancer and localised chronic pancreatitis can be difficult. The main role of ERCP is to insert a stent into the common bile duct to relieve obstructive jaundice in inoperable patients.

Management

Surgical resection is the only method of effecting cure, and 5-year survival in patients undergoing a complete resection is around 12%. Clinical trials have demonstrated improved survival (21–29%) with adjuvant chemotherapy using gemcitabine. Unfortunately, only 10–15% of tumours are resectable for cure, since most are locally advanced at the time of diagnosis. For the great majority of patients, treatment is palliative. Chemotherapy with FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan and oxaliplatin) improves median survival to 11 months. Pain relief can be achieved using analgesics but, in some patients, coeliac plexus neurolysis may be required. Jaundice can be relieved by choledochojunostomy in fit patients, whereas percutaneous or endoscopic stenting is preferable in the elderly and those with very advanced disease. Ampullary or periampullary adenocarcinomas are rare neoplasms that arise from the ampulla of Vater or adjacent duodenum. They are often polypoid and may ulcerate; they frequently infiltrate the duodenum but behave less aggressively than pancreatic adenocarcinoma. Around 25% of patients undergoing resection
Fig. 21.69 Features of pancreatic cancer.

Fig. 21.70 Carcinoma of the pancreas. A A computed tomogram showing a large, necrotic mass encasing the coeliac axis (arrows). B Endoscopic ultrasound was subsequently performed to enhance staging and to obtain a fine needle aspiration biopsy, which confirmed pancreatic ductal adenocarcinoma.
Incidental pancreatic mass

Cystic neoplasms of the pancreas are increasingly being seen with widespread use of CT. These are a heterogeneous group; serous cystadenomas rarely, if ever, become malignant and do not require surgery. Mucinous cysts occur more often in women, are usually in the pancreatic tail and display a spectrum of behaviour from benign to frankly malignant. Aspiration of the cyst contents for cytology and measurement of CEA and amylase concentrations in fluid obtained at EUS can help determine whether a lesion is mucinous or not. In fit patients, all mucinous lesions should be resected. A variant, called intraductal papillary mucinous neoplasia (IPMN), is often discovered coincidentally on CT, frequently in elderly men. This may affect the main pancreatic duct with marked dilatation and plugs of mucus, or may involve a side branch. The histology varies from villous adenomatous change to dysplasia or carcinoma. Since IPMN is a pre-malignant but indolent condition, the decision to resect or to monitor depends on age and fitness of the patient and location, size and evolution of lesions.

Clinical examination of the abdomen for liver and biliary disease

History and significance of abdominal signs

### Presenting clinical features of liver disease

These represent the combined effects of:

**Impairment of liver function and its metabolic sequelae**
- Jaundice (failure of bilirubin clearance)
- Encephalopathy (failure of clearance of by-products of metabolism)
- Bleeding (impaired liver synthesis of clotting factors)
- Hypoglycaemia

**Ongoing presence of aetiological factors (e.g. alcohol)**
- Effects of aetiological agent, e.g. intoxication, withdrawal, cognitive impairment versus
- Effects of liver injury from agent, e.g. encephalopathy

**Effects of chronic liver injury (>6 months)**
- Catabolic status (± poor nutrition)
- Skin thinning (‘paper-money skin’)
- Loss of muscle bulk
- Leucopenia
- Impaired albumin synthesis
- Reduced oncocotic pressure (contributes to ascites)
- Reduced aldosterone clearance
- Na⁺ retention (contributes to ascites)
- Reduced oestrogen clearance
- Mild feminisation of males (loss of body hair, gynaecomastia)

---

### Silent presentation of liver disease

It is important to note that patients with liver disease can present silently following detection of abnormality on screening investigation. This occurs frequently in practice in three settings:

**Biochemical abnormality**
- Liver enzyme abnormality detected during health screening or drug monitoring

**Radiological abnormality**
- Observation of an unexpected structural lesion (liver mass most usually) following ultrasound, computed tomography or other imaging assessment undertaken for reasons unrelated to the liver

**Serological abnormality**
- Detection of a liver-related autoantibody

### Aspects

**Causes**

**Exudative (high protein)**
- Carcinoma
- Tuberculosis

**Transudative (low protein)**
- Cirrhosis
- Renal failure (including nephrotic syndrome)
- Congestive heart failure

**Associated clinical findings**
- Weight loss ± hepatomegaly
- Weight loss ± fever
- Hepatomegaly
- Splenomegaly
- Spider naevi
- Generalised oedema
- Peripheral oedema
- Elevated jugular venous pressure

### Assessment of liver size

Clinical assessment of hepatomegaly is important in diagnosing liver disease.
- Start in the right iliac fossa.
- Progress up the abdomen 2 cm with each breath (through open mouth).
- Confirm the lower border of the liver by percussion.
- Detect if smooth or irregular, tender or non-tender; ascertain the shape.
- Identify the upper border by percussion.

---

### Assessment of encephalopathy

**Flapping tremor.** Jerky forward movements every 5–10 secs, when arms are outstretched and hands are dorsiflexed, suggest hepatic encephalopathy. The movements are coarser than those seen in tremor.

**Number connection test.** These 25 numbered circles can normally be joined together within 30 secs. Serial observations may provide useful information, as long as the position of the numbers is varied to avoid the patient learning their pattern.

**Constructional apraxia.** Drawing stars and clocks may reveal marked abnormality.
**Functional anatomy and physiology**

**Applied anatomy**

### Normal liver structure and blood supply

The liver weighs 1.2–1.5 kg and has multiple functions, including key roles in metabolism, control of infection, and elimination of toxins and by-products of metabolism. It is classically divided into left and right lobes by the falciform ligament, but a more useful functional division is into the right and left hemilivers, based on blood supply (Fig. 22.1). These are further divided into eight segments, according to subdivisions of the hepatic and portal veins. Each segment has its own branch of the hepatic artery and portal vein.

![Liver blood supply](image1)

**Fig. 22.1** Liver blood supply.

Blood flows into the acinus via a single branch of the portal vein and hepatic artery situated centrally in the portal tracts. Blood flows outwards along the hepatic sinusoids into one of several tributaries of the hepatic vein at the periphery of the acinus. Bile, formed by active and passive excretion by hepatocytes into channels called cholangioles, which lie between them, flows in the opposite direction from the periphery of the acinus. The cholangioles converge in interlobular bile ducts in the portal tracts.

The hepatocytes in each acinus lie in three zones, depending on their position relative to the portal tract. Those in zone 1 are closest to the terminal branches of the portal vein and hepatic artery, and are richly supplied with oxygenated blood, and with blood containing the highest concentration of nutrients and toxins. Conversely, hepatocytes in zone 3 are furthest from the portal tracts and closest to the hepatic veins, and are therefore relatively hypoxic and exposed to lower concentrations of nutrients and toxins compared to zone 1. The different perfusion and toxin exposure patterns, and thus vulnerability, of hepatocytes in the different zones contribute to the often patchy nature of liver injury.

**Liver cells**

Hepatocytes comprise 80% of liver cells. The remaining 20% are the endothelial cells lining the sinusoids, epithelial cells lining the intrahepatic bile ducts, cells of the immune system (including macrophages (Kupffer cells) and unique populations of atypical lymphocytes), and a key population of non-parenchymal cells called stellate or Ito cells.

![Liver structure and microstructure](image2)

**Fig. 22.2** Liver structure and microstructure. **A** Liver anatomy showing relationship with pancreas, bile duct and duodenum. **B** Hepatic lobule. **C** Hepatic acinus.
Endothelial cells line the sinusoids (Fig. 22.3), a network of capillary vessels that differ from other capillary beds in the body, in that there is no basement membrane. The endothelial cells have gaps between them (fenestrae) of about 0.1 micron in diameter, allowing free flow of fluid and particulate matter to the hepatocytes. Individual hepatocytes are separated from the leaky sinusoids by the space of Disse, which contains stellate cells that store vitamin A and play an important part in regulating liver blood flow. They may also be immunologically active and play a role in the liver’s contribution to defence against pathogens. The key role of stellate cells in terms of pathology is in the development of hepatic fibrosis, the precursor of cirrhosis. They undergo activation in response to cytokines produced following liver injury, differentiating into myofibroblasts, which are the major producers of the collagen-rich matrix that forms fibrous tissue (Fig. 22.4).

**Blood supply**

The liver is unique as an organ, as it has dual perfusion: it receives a majority of its supply via the portal vein, which drains blood from the gut via the splanchnic circulation and is the principal route for nutrient trafficking to the liver, and a minority from the hepatic artery. The portal venous contribution is 50–90%. The dual perfusion system, and the variable contribution from portal vein and hepatic artery, can have important effects on the clinical expression of liver ischaemia (which typically exhibits a less dramatic pattern than ischaemia in other organs, a fact that can sometimes lead to it being missed clinically), and can raise practical challenges in liver transplant surgery.

**Biliary system and gallbladder**

Hepatocytes provide the driving force for bile flow by creating osmotic gradients of bile acids, which form micelles in bile (bile

![Fig. 22.3 Non-parenchymal liver cells. (B cell = B lymphocyte; NK cell = natural killer cell; PMN cell = polymorphonuclear leucocyte; T cell = T lymphocyte).](image)

![Fig. 22.4 Pathogenic mechanisms in hepatic fibrosis. Stellate cell activation occurs under the influence of cytokines released by other cell types in the liver, including hepatocytes, Kupffer cells (tissue macrophages), platelets and lymphocytes. Once stellate cells become activated, they can perpetuate their own activation by synthesis of transforming growth factor beta (TGF-β), and platelet-derived growth factor (PDGF) through autocrine loops. Activated stellate cells produce TGF-β1, stimulating the production of collagen matrix, as well as inhibitors of collagen breakdown. The inhibitors of collagen breakdown, matrix metalloproteinase 2 and 9 (MMP2 and MMP9), are inactivated in turn by tissue inhibitors TIMP1 and TIMP2, which are increased in fibrosis. Inflammation also contributes to fibrosis, with the cytokine profile produced by Th2 lymphocytes, such as interleukin-6 and 13 (IL-6 and IL-13). Activated stellate cells also produce endothelin 1 (ET1), which may contribute to portal hypertension. (EGF = epidermal growth factor; IGF1 = insulin-like growth factor 1; ROS = reactive oxygen species).](image)
acid-dependent bile flow, and of sodium (bile acid-independent bile flow). Bile is secreted by hepatocytes and flows from cholangioles to the biliary canaliculi. The canaliculi join to form larger intrahepatic bile ducts, which in turn merge to form the right and left hepatic ducts. These ducts join as they emerge from the liver to form the common hepatic duct, which becomes the common bile duct after joining the cystic duct (see Fig. 22.2). The common bile duct is approximately 5 cm long and 4–6 mm wide. The distal portion of the duct passes through the head of the pancreas and usually joins the pancreatic duct before entering the duodenum through the ampullary sphincter (sphincter of Oddi). It should be noted, though, that the anatomy of the lower common bile duct can vary widely. Common bile duct pressure is maintained by rhythmic contraction and relaxation of the sphincter of Oddi; this pressure exceeds gallbladder pressure in the fasting state, so that bile normally flows into the gallbladder, where it is concentrated 10-fold by resorption of water and electrolytes.

The gallbladder is a pear-shaped sac typically lying under the right hemiliver, with its fundus located anteriorly behind the tip of the 9th costal cartilage. Anatomical variation is common and should be considered when assessing patients clinically and radiologically. The function of the gallbladder is to concentrate, and provide a reservoir for, bile. Gallbladder tone is maintained by vagal activity, and cholecystokinin released from the duodenal mucosa during feeding causes gallbladder contraction and reduces sphincter pressure, so that bile flows into the duodenum. The body and neck of the gallbladder pass posteromedially towards the porta hepatis, and the cystic duct then joins it to the common hepatic duct. The cystic duct mucosa has prominent crescentic folds (valves of Heister), giving it a beaded appearance on cholangiography.

**Hepatic function**

**Carbohydrate, amino acid and lipid metabolism**

The liver plays a central role in carbohydrate, lipid and amino acid metabolism, and is also involved in metabolising drugs and environmental toxins (Fig. 22.5). An important and increasingly recognised role for the liver is in the integration of metabolic pathways, regulating the response of the body to feeding and starvation. Abnormality in metabolic pathways and their regulation can play an important role both in liver disease (e.g. non-alcoholic fatty liver disease, NAFLD) and in diseases that are not conventionally regarded as diseases of the liver (such as type 2 diabetes and inborn errors of metabolism). Hepatocytes have specific pathways to handle each of the nutrients absorbed from the gut and carried to the liver via the portal vein:

- Amino acids from dietary proteins are used for synthesis of plasma proteins, including albumin. The liver produces 8–14 g of albumin per day, and this plays a critical role in maintaining oncotic pressure in the vascular space and in the transport of small molecules like bilirubin, hormones and drugs throughout the body. Amino acids that are not required for the production of new proteins are broken down, with the amino group being converted ultimately to urea.
- Following a meal, more than half of the glucose absorbed is taken up by the liver and stored as glycogen or converted to glycerol and fatty acids, thus preventing hyperglycaemia. During fasting, glucose is synthesised (gluconeogenesis) or released from glycogen in the liver, thereby preventing hypoglycaemia (p. 724).

- The liver plays a central role in lipid metabolism, producing very low-density lipoproteins and further metabolising low- and high-density lipoproteins (see Fig. 14.13, p. 372). Dysregulation of lipid metabolism is thought to have a critical role in the pathogenesis of NAFLD. Lipids are now recognised to play a key part in the pathogenesis of hepatitis C, facilitating viral entry into hepatocytes.

**Clotting factors**

The liver produces key proteins that are involved in the coagulation cascade. Many of these coagulation factors (II, VII, IX and X) are post-translationally modified by vitamin K-dependent enzymes, and their synthesis is impaired in vitamin K deficiency (p. 918). Reduced clotting factor synthesis is an important and easily accessible biomarker of liver function in the setting of liver injury. Prothrombin time (PT; or the International Normalised Ratio, INR) is therefore one of the most important clinical tools available for the assessment of hepatocyte function. Note that the deranged PT or INR seen in liver disease may not directly equate to increased bleeding risk, as these tests do not capture the concurrent reduced synthesis of anticoagulant factors, including protein C and protein S. In general, therefore, correction of PT using blood products before minor invasive procedures should be guided by clinical risk rather than the absolute value of the PT.

**Bilirubin metabolism and bile**

The liver plays a central role in the metabolism of bilirubin and is responsible for the production of bile (Fig. 22.6). Between 425 and 510 mmol (250–300 mg) of unconjugated bilirubin is produced from the catabolism of haem daily. Bilirubin in the
Vitamin K is a fat-soluble vitamin and so the inability to absorb compounds, e.g. 7-dehydrocholesterol to 25(OH) vitamin D. The liver is also able to metabolise vitamins to more active amounts and disappear rapidly if dietary intake is reduced. while others, such as vitamin K and folate, are stored in smaller amounts, e.g. 7-dehydrocholesterol to 25(OH) vitamin D. The liver is also able to metabolise vitamins to more active amounts and disappear rapidly if dietary intake is reduced. Vitamin A, D and B₁₂ are stored by the liver in large amounts, while others, such as vitamin K and folate, are stored in smaller amounts and disappear rapidly if dietary intake is reduced. Vitamin K is a fat-soluble vitamin and so the inability to absorb fat-soluble vitamins, as occurs in biliary obstruction, results in a coagulopathy. The liver also stores minerals such as iron, in ferritin and haemosiderin, and copper, which is excreted in bile.

**Immune regulation**

Approximately 9% of the normal liver is composed of immune cells (see Fig. 22.3). Cells of the innate immune system include Kupffer cells derived from blood monocytes, the liver macrophages and natural killer (NK) cells, as well as ‘classical’ B and T cells of the adaptive immune response (p. 67). An additional type of atypical lymphocyte, with phenotypic features of both T cells and NK cells, is thought to play an important role in host defence through linking of innate and adaptive immunity. The enrichment of such cells in the liver reflects the unique importance of the liver in preventing microorganisms from the gut from entering the systemic circulation.

Kupffer cells constitute the largest single mass of tissue-resident macrophages in the body and account for 80% of the phagocytic capacity of this system. They remove aged and damaged red blood cells, bacteria, viruses, antigen–antibody complexes and endotoxin. They also produce a wide variety of inflammatory mediators that can act locally or may be released into the systemic circulation.

The immunological environment of the liver is unique in that antigens presented within it tend to induce immunological tolerance. This is of importance in liver transplantation, where classical major histocompatibility (MHC) barriers may be crossed, and also in chronic viral infections, when immune responses may be attenuated. The mechanisms that underlie this phenomenon have not been fully defined.

### Storage of vitamins and minerals

Vitamins A, D and B₁₂ are stored by the liver in large amounts, while others, such as vitamin K and folate, are stored in smaller amounts and disappear rapidly if dietary intake is reduced. The liver is also able to metabolise vitamins to more active compounds, e.g. 7-dehydrocholesterol to 25(OH) vitamin D. Vitamin K is a fat-soluble vitamin and so the inability to absorb
Investigation of liver and hepatobiliary disease

Investigations play an important role in the management of liver disease in three settings:

- identifying the presence of liver disease
- establishing the aetiology
- understanding disease severity (in particular, identification of cirrhosis with its complications).

When planning investigations, it is important to be clear as to which of these goals is being addressed.

Suspicion of the presence of liver disease is normally based on blood biochemistry abnormality (‘liver function tests’, or ‘LFTs’).

Aetiology is typically established through a combination of history, specific blood tests and, where appropriate, imaging and liver biopsy.

Staging of disease (in essence, the identification of cirrhosis) is largely histological, although there is increasing interest in non-invasive approaches, including novel imaging modalities, serum markers of fibrosis and the use of predictive scoring systems.

The aims of investigation in patients with suspected liver disease are shown in Box 22.1.

Liver blood biochemistry

Liver blood biochemistry (LFTs) includes the measurement of serum bilirubin, aminotransferases, alkaline phosphatase, γ-glutamyl transferase and albumin. Most analytes measured by LFTs are not truly ‘function’ tests but instead, given that they are released by injured hepatocytes, provide biochemical evidence of liver cell damage. Liver function per se is best assessed by the clearance of bilirubin. Although LFT abnormalities are often non-specific, the patterns are frequently helpful in directing further investigations. In addition, levels of bilirubin and albumin and the PT are related to clinical outcome in patients with severe liver disease, reflected by their use in several prognostic scores: the Child–Pugh and MELD scores in cirrhosis (see Boxes 22.29 and 22.30, pp. 867 and 868), the Glasgow score in alcoholic hepatitis (see Box 22.47, p. 882) and the King’s College Hospital criteria for liver transplantation in acute liver failure (see Box 22.11, p. 858). These established predictive models, together with different enzymes that hydrolyse phosphate esters at alkaline pH. These enzymes are widely distributed in the body but the main sites of production are the liver, gastrointestinal tract, bone, placenta and kidney. ALPs are post-translationally modified, resulting in the production of several different isoenzymes, which differ in abundance in different tissues. ALP enzymes in the liver are located in cell membranes of the hepatic sinusoids and the biliary canaliculi. Accordingly, levels rise with intrahepatic and extrahepatic biliary obstruction and with sinusoidal obstruction, as occurs in infiltrative liver disease.

Gamma-glutamyl transferase (GGT) is a microsomal enzyme found in many cells and tissues of the body. The highest concentrations are located in the liver, where it is produced by hepatocytes and by the epithelium lining small bile ducts. The function of GGT is to transfer glutamyl groups from γ-glutamyl peptides to other peptides and amino acids.

The pattern of a modest increase in aminotransferase activity and large increases in ALP and GGT activity favours biliary obstruction and is commonly described as ‘cholestatic’ or ‘obstructive’ (Box 22.2). Isolated elevation of the serum GGT is relatively common and may occur during ingestion of microsomal enzyme-inducing drugs, including alcohol (Box 22.3), but also in NAFLD.

Other biochemical tests

Other widely available biochemical tests may become altered in patients with liver disease:

- Hyponatraemia occurs in severe liver disease due to increased production of vasopressin (antidiuretic hormone,
ADH; see Fig. 14.8, p. 359). Hyponatraemia can be a significant clinical problem in liver disease with aspects that are distinct from hyponatraemia of other causes.

- Serum urea may be reduced in hepatic failure, whereas levels of urea may be increased following gastrointestinal haemorrhage.
- When high levels of urea are accompanied by raised bilirubin, high serum creatinine and low urinary sodium, this suggests hepatorenal failure, which carries a grave prognosis.
- Significantly elevated ferritin suggests haemochromatosis. Modest elevations can be seen in inflammatory disease, NAFLD and alcohol excess.

### Haematological tests

#### Blood count

The peripheral blood count is often abnormal and can give a clue to the underlying diagnosis:

- **A normochromic normocytic anaemia** may reflect recent gastrointestinal haemorrhage, whereas chronic blood loss is characterised by a hypochromic microcytic anaemia secondary to iron deficiency. A high erythrocyte mean cell volume (macrocytosis) is associated with alcohol misuse, but target cells in any jaundiced patient also result in a macrocytosis. Macrocytosis can persist for a long period of time after alcohol cessation, making it a poor marker of ongoing consumption.
- **Leucopenia** may complicate portal hypertension and hypersplenism, whereas leucocytosis may occur with cholangitis, alcoholic hepatitis and hepatic abscesses. Atypical lymphocytes are seen in infectious mononucleosis, which may be complicated by an acute hepatitis.
- **Thrombocytopenia** is common in cirrhosis and is due to reduced platelet production and increased breakdown because of hypersplenism. Thrombopoietin, required for platelet production, is produced in the liver and levels fall with worsening liver function. Thus platelet levels are usually more depressed than white cells and haemoglobin in the presence of hypersplenism in patients with cirrhosis.

A low platelet count is often an indicator of chronic liver disease, particularly in the context of hepatomegaly. Thrombocytosis is unusual in patients with liver disease but may occur in those with active gastrointestinal haemorrhage and, rarely, in hepatocellular carcinoma.

#### Coagulation tests

These are often abnormal in patients with liver disease. The normal half-lives of the vitamin K-dependent coagulation factors in the blood are short (5–72 hours), and so changes in the PT occur relatively quickly following liver damage; these changes provide valuable prognostic information in patients with both acute and chronic liver failure. An increased PT is evidence of severe liver damage in chronic liver disease. Vitamin K does not reverse this deficiency if it is due to liver disease, but will correct the PT if the cause is vitamin K deficiency, as may occur with biliary obstruction due to non-absorption of fat-soluble vitamins.

#### Immunological tests

A variety of tests are available to evaluate the aetiology of hepatic disease (Boxes 22.4 and 22.5). The presence of liver-related autoantibodies can be suggestive of the presence of autoimmune liver disease (although false-positive results can occur in non-autoimmune inflammatory disease such as NAFLD). Elevation in overall serum immunoglobulin levels can also indicate autoimmunity (immunoglobulin G (IgG) and IgM). Elevated serum IgA can be seen, often in more advanced alcoholic liver disease and NAFLD, although the association is not specific.

#### Imaging

Several imaging techniques can be used to determine the site and general nature of structural lesions in the liver and biliary tree. In general, however, imaging techniques are unable to identify hepatic inflammation and have poor sensitivity for liver fibrosis unless advanced cirrhosis with portal hypertension is present.

#### Ultrasound

Ultrasound is non-invasive and most commonly used as a ‘first-line’ test to identify gallstones, biliary obstruction (Fig. 22.8) or thrombosis in the hepatic vasculature. Ultrasound is good for the identification of splenomegaly and abnormalities in liver texture but is less effective at identifying diffuse parenchymal disease. Focal lesions, such as tumours, may not be detected if they are less than 2 cm in diameter and have similar echogenicity to normal liver tissue. Bubble-based contrast media are now used routinely and can enhance discriminant capability. Doppler ultrasound allows blood flow in the hepatic artery, portal vein...
Hepatic angiography is seldom used nowadays as a diagnostic tool, since CT and MRI are both able to provide images of hepatic vasculature, but it still has a therapeutic role in the embolisation of vascular tumours, such as hepatocellular carcinoma. Hepatic venography is now rarely performed.

**Cholangiography**

Cholangiography can be undertaken by magnetic resonance cholangiopancreatography (MRCP; Fig. 22.10), endoscopy (endoscopic retrograde cholangiopancreatography, ERCP) or the percutaneous approach (percutaneous transhepatic
The biopsy is obtained by the transjugular route,
and the defect is corrected with fresh frozen plasma and
in patients with defective haemostasis if:

- obstruction of a large bile duct. Liver biopsies can be carried
- rare and usually occurs when a biopsy is performed in a patient
- shoulder pain, bleeding and biliary peritonitis. Biliary peritonitis is
- about 0.01%. The main complications are abdominal and/or
- diagnostic ERCP. Both endoscopic and percutaneous approaches allow
- tree but is safer, and there is now little, if any, role for diagnostic
- MRCP is as good as ERCP at providing images of the biliary
to Vater or pancreatic duct to be visualised. Endoscopic ultrasound
- the procedure is conducted percutaneously under ultrasound control and the needle track is then plugged
- the main causes are complex, with several features occurring together, liver disorders can be
- broadly classified histologically into fatty liver (steatosis), hepatitis (inflammation, 'grade') and cirrhosis (fibrosis, 'stage'). The use of
- special histological stains can help in determining aetiology. The clinical features and prognosis of these changes are dependent
- only if it is not possible to access the bile duct endoscopically.

**Histological examination**

An ultrasound-guided liver biopsy can confirm the severity of liver damage and provide aetiological information. It is performed percutaneously with a Trucut or Menghini needle, usually through an intercostal space under local anaesthesia, or radiologically using a transjugular approach.

Percutaneous liver biopsy is a relatively safe procedure if the conditions detailed in Box 22.6 are met, but carries a mortality of about 0.01%. The main complications are abdominal and/or shoulder pain, bleeding and biliary peritonitis. Biliary peritonitis is rare and usually occurs when a biopsy is performed in a patient with obstruction of a large bile duct. Liver biopsies can be carried out in patients with defective haemostasis if:

- the defect is corrected with fresh frozen plasma and platelet transfusion
- the biopsy is obtained by the transjugular route, or

**Endoscopic ultrasound**

Endoscopic ultrasound (EUS; p. 774) is complementary to MRCP in the diagnostic evaluation of the extrahepatic biliary tree, ampulla of Vater and pancreas. With the ultrasonic probe in the duodenum, high-quality images are obtained, tissue sampling can be performed and, increasingly, therapeutic drainage of biliary obstruction can be performed. EUS has the advantage over ERCP of not exposing patients to the risk of pancreatitis, among other complications of bile duct cannulation.

**Non-invasive markers of hepatic fibrosis**

Non-invasive markers of liver fibrosis can reduce the need for liver biopsy to assess the extent of fibrosis in some settings. In general, they have high negative predictive value, being able to exclude the presence of advanced fibrosis, but a relatively low positive predictive value. It is important to note that many of these tests have been validated only in certain aetiologies of liver disease and therefore results cannot be extrapolated to all other liver diseases. Alcohol-related liver disease is particularly poorly served in this respect.

Serological markers of hepatic fibrosis, such as α2-macroglobulin, haptoglobin and routine biochemical tests, are used in the Fibrotest®. The Enhanced Liver Fibrosis (ELF®) serological assay uses a combination of hyaluronic acid, procollagen peptide III (PIINP) and tissue inhibitor of metalloprotease 1 (TIMP1). These tests are good at differentiating severe fibrosis from mild scarring but are limited in their ability to detect subtle changes. A number of non-commercial scores based on standard biochemical and anthropometric indices have also been described that provide similar levels of sensitivity and specificity (e.g. the FIB4 score, which is based on age, ALT/AST ratio and platelet count).

An alternative to serological markers is vibration-controlled transient elastography (Fibroscan®), in which ultrasound-based shock waves are sent through the liver to measure liver stiffness as a surrogate for hepatic fibrosis. Once again, this test is good at differentiating severe fibrosis from mild scarring, but it is limited in its ability to detect subtle changes and validity may be affected by obesity. Similar techniques, including magnetic resonance elastography, are promising but not yet widely available.

**Presenting problems in liver disease**

Liver injury may be either acute or chronic. The main causes are listed in Figure 22.11 and discussed in detail later in the chapter. In
the UK, liver disease is the only one of the top causes of mortality that is steadily increasing (Fig. 22.12). Mortality rates have risen substantially over the last 30 years, with a near-fivefold increase in liver-related mortality in people younger than 65 years. The rate of increase is substantially higher in the UK than in other countries in Western Europe.

- Acute liver injury may present with non-specific symptoms of fatigue and abnormal LFTs, or with jaundice and acute liver failure.
- Chronic liver injury is defined as hepatic injury, inflammation and/or fibrosis occurring in the liver for more than 6 months. In the early stages, patients can be asymptomatic with fluctuating abnormal LFTs. With more severe liver damage, however, the presentation can be with jaundice, portal hypertension or other signs of cirrhosis and hepatic decompensation (Box 22.7). Patients with clinically silent chronic liver disease frequently present when abnormalities in liver function are observed on routine blood testing, or when clinical events, such as an intercurrent infection or surgical intervention, cause the liver to decompensate. Patients with compensated cirrhosis can undergo most forms of surgery without

significantly increased risk, whereas decompensation can be a complication in all cases and the presence of portal hypertension with intra-abdominal varices can make abdominal surgery more hazardous. The possibility of undiagnosed liver disease should be borne in mind in all patients in at-risk groups undergoing significant surgery.

**Acute liver failure**

Acute liver failure is an uncommon but serious condition characterised by a relatively rapid progressive deterioration in liver function. The presence of encephalopathy is a cardinal feature, with mental changes progressing from delirium to coma. The syndrome was originally defined further as occurring within 8 weeks of onset of the precipitating illness, in the absence of evidence of pre-existing liver disease. This distinguishes it from instances in which hepatic encephalopathy represents a deterioration in chronic liver disease.

Liver failure occurs when there is insufficient metabolic and synthetic function for the needs of the patient. Although the direct cause is usually acute loss of functional hepatocytes, this can occur in different settings, which have implications for outcome and treatment. In a patient whose liver was previously normal (fulminant liver failure), the level of injury needed to cause liver

**Fig. 22.12** Standardised UK mortality rates showing the rise in liver-related mortality.

Presenting problems in liver disease

Clinical assessment

Cerebral disturbance (hepatic encephalopathy and/or cerebral oedema) is the cardinal manifestation of acute liver failure, but in the early stages this can be mild and episodic, and so its absence does not exclude a significant acute liver injury. The initial clinical features are often subtle and include reduced alertness and poor concentration, progressing through behavioural abnormalities, such as restlessness and aggressive outbursts, to drowsiness and coma (Box 22.9). Cerebral oedema may occur due to increased intracranial pressure, causing unequal or abnormally reacting pupils, fixed pupils, hypertensive episodes, bradycardia, hyperventilation, profuse sweating, local or general myoclonus, focal fits or decerebrate posturing. Papilloedema occurs rarely and is a late sign. More general symptoms include weakness, nausea and vomiting. Right hypochondrial discomfort is an occasional feature.

The patient may be jaundiced but jaundice may not be present at the outset (e.g. in paracetamol overdose), and there are a number of exceptions, including Reye’s syndrome, in which jaundice is rare. Occasionally, death may occur in fulminant cases of acute liver failure before jaundice develops. Fetor hepaticus can be present. The liver is usually of normal size but later becomes smaller. Hepatomegaly is unusual and, in

Pathophysiology

Any cause of liver damage can produce acute liver failure, provided it is sufficiently severe (Fig. 22.13). Acute viral hepatitis is the most common cause worldwide, whereas paracetamol toxicity (p. 137) is the most frequent cause in the UK. Acute liver failure occurs occasionally with other drugs, or from Amanita phalloides (mushroom) poisoning, in pregnancy, in Wilson’s disease, following shock (p. 199) and, rarely, in extensive malignant disease of the liver. In 10% of cases, the cause of acute liver failure remains unknown and these patients are often labelled as having ‘non-A–E viral hepatitis’ or ‘cryptogenic’ acute liver failure.
the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd–Chiari syndrome, p. 898). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy. Other features are related to the development of complications (see below).

**Investigations**

The patient should be investigated to determine the cause of the liver failure and the prognosis (Boxes 22.10 and 22.11). Hepatitis B core IgM antibody is the best screening test for acute hepatitis B infection, as liver damage is due to the immunological response to the virus, which has often been eliminated, and the test for hepatitis B surface antigen (HBsAg) may be negative. The PT rapidly becomes prolonged as coagulation factor synthesis fails; this is the laboratory test of greatest prognostic value and should be carried out at least twice daily. Its prognostic importance emphasises the necessity of avoiding the use of fresh frozen plasma to correct raised PT in acute liver failure, except in the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd–Chiari syndrome, p. 898). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy. Other features are related to the development of complications (see below).

**Management**

Patients with acute liver failure should be treated in a high-dependency or intensive care unit as soon as progressive prolongation of the PT occurs or hepatic encephalopathy is identified (Box 22.12), so that prompt treatment of complications can be initiated (Box 22.13). Conservative treatment aims to maintain life in the hope that hepatic regeneration will occur, but early transfer to a specialised transplant unit should always be considered. N-acetylcysteine therapy may improve outcome, particularly in patients with acute liver failure due to paracetamol poisoning. Liver transplantation is an increasingly important treatment option for acute liver failure, and criteria have been developed to identify patients unlikely to survive without a transplant (see Box 22.11). Patients should, wherever possible, be transferred to a transplant centre before these criteria are met to allow time for assessment and to maximise the time for a donor liver to become available. Survival following liver transplantation bilirubin reflects the degree of jaundice. Plasma aminotransferase activity is particularly high after paracetamol overdose, reaching 100–500 times normal, but falls as liver damage progresses and is not helpful in determining prognosis. Plasma albumin remains normal unless the course is prolonged. Percutaneous liver biopsy is contraindicated because of the severe coagulopathy, but biopsy can be undertaken using the transjugular route if appropriate.

**Infection surveillance**

- Cultures: blood, urine, throat, sputum, cannula sites
- Chest X-ray
- Temperature
for acute liver failure is improving and 1-year survival rates of about 60% can be expected. A number of artificial liver support systems have been developed and evaluated for use as a bridge to either transplantation or recovery. None, however, has entered routine clinical use.

### Abnormal liver function tests

Frequently, LFTs are requested in patients who have no symptoms or signs of liver disease, as part of routine health checks, insurance medicals or drug monitoring. When abnormal results are found, it is important for the clinician to be able to interpret them and to investigate appropriately. Many patients with chronic liver disease are asymptomatic or have vague, non-specific symptoms. Apparently asymptomatic abnormal LFTs are therefore a common occurrence. When LFTs are measured routinely prior to elective surgery, 3.5% of patients are discovered to have mildly elevated transaminases. The prevalence of abnormal LFTs has been reported to be as high as 10% in some studies. The most common abnormalities are alcoholic (p. 880) or non-alcoholic fatty liver disease (p. 882). Since effective medical treatments are now available for many types of chronic liver disease, further evaluation is usually warranted to make sure the patient does not have a treatable condition. Although transient mild abnormalities in LFTs may not be clinically significant, the majority of individuals with persistently abnormal LFTs do have significant liver disease. Biochemical abnormalities in chronic liver disease often fluctuate over time; even mild abnormalities can therefore indicate significant underlying disease and so warrant follow-up and investigation.

When abnormal LFTs are detected, a thorough history should be compiled to determine the patient’s alcohol consumption, drug use (prescribed drugs or otherwise), risk factors for viral hepatitis (e.g. blood transfusion, injection drug use, tattoos), the presence of autoimmune diseases, family history, neurological symptoms, and the presence of features of the metabolic syndrome (p. 730), including diabetes and/or obesity (see Box 22.5 and Fig. 19.5, p. 698). The presence or absence of stigmata of liver disease is not always an indication of chronic liver disease.

chronic liver disease does not reliably identify those individuals with significant disease and investigations are indicated, even in the absence of these signs.

Both the pattern of LFT abnormality (hepatitic or obstructive) and the degree of elevation are helpful in determining the cause of underlying liver disease (Boxes 22.14 and 22.15). The investigations that make up standard liver screen and additional or confirmatory tests are shown in Boxes 22.4 and 22.5. An algorithm for investigating abnormal LFTs is provided in Figure 22.14.

### Jaundice

Jaundice is usually detectable clinically when the plasma bilirubin exceeds 40 μmol/L (~2.5 mg/dL). The causes of jaundice overlap with the causes of abnormal LFTs discussed above. In a patient with jaundice it is useful to consider whether the cause might be pre-hepatic, hepatic or post-hepatic, and there are often important clues in the history (Box 22.16).

#### Pre-hepatic jaundice

This is caused either by haemolysis or by congenital hyperbilirubinaemia, and is characterised by an isolated raised bilirubin level.

### Hepatocellular jaundice

Hepatocellular jaundice results from an inability of the liver to transport bilirubin into the bile, occurring as a consequence of parenchymal disease. Bilirubin transport across the hepatocytes may be impaired at any point between uptake of unconjugated bilirubin into the cells and transport of conjugated bilirubin into the canaliculi. In addition, swelling of cells and oedema resulting from the disease itself may cause obstruction of the biliary canaliculi. In hepatocellular jaundice, the concentrations of both unconjugated and conjugated bilirubin in the blood increase.

*Symptoms may be absent and abnormal liver function tests detected incidentally.
Presenting problems in liver disease

Hepatocellular jaundice can be due to acute or chronic injury (see Fig. 22.11), and clinical features of acute or chronic liver disease may be detected clinically (see Box 22.7).

Characteristically, jaundice due to parenchymal liver disease is associated with increases in transaminases (AST, ALT), but increases in other LFTs, including cholestatic enzymes (GGT, ALP), may occur and suggest specific aetiologies (see below). Acute jaundice in the presence of an ALT of >1000 U/L is highly suggestive of an infectious cause (e.g. hepatitis A or B), drugs (e.g. paracetamol) or hepatic ischaemia. Imaging is essential, in particular to identify features suggestive of cirrhosis, define the patency of the hepatic vasculature and obtain evidence of portal hypertension. Liver biopsy has an important role in defining the aetiology of hepatocellular jaundice and the extent of liver injury.

Obstructive (cholestatic) jaundice

Cholestatic jaundice may be caused by:
- failure of hepatocytes to initiate bile flow
- obstruction of the bile ducts or portal tracts
- obstruction of bile flow in the extrahepatic bile ducts between the porta hepatis and the papilla of Vater.

In the absence of treatment, cholestatic jaundice tends to become progressively more severe because conjugated bilirubin is unable to enter the bile canaliculi and passes back into the blood, and also because there is a failure of clearance of unconjugated bilirubin arriving at the liver cells. The causes of cholestatic jaundice are listed in Box 22.15. Cholestasis may result from defects at more than one of these levels. Those confined to the extrahepatic bile ducts may be amenable to surgical or endoscopic correction.

Clinical features (Box 22.18) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 22.19). Obstruction of the bile duct drainage due to blockage of the extrahepatic biliary tree is characteristically associated with pale stools and dark urine. Pruritus may be a dominant feature and can be accompanied by skin excoriations. Peripheral stigmata of chronic liver disease are absent. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically inflamed, stone-containing gallbladder cannot readily dilate. This is Courvoisier’s Law, and suggests

Fig. 22.15 Investigation of jaundice. (ERCP = endoscopic retrograde cholangiopancreatography; LFTs = liver function tests; MRCP = magnetic resonance cholangiopancreatography)
that jaundice is due to a malignant biliary obstruction (e.g. pancreatic cancer). Cholangitis is characterised by ‘Charcot’s triad’ of jaundice, right upper quadrant pain and fever. Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than the aminotransferases.

Ultrasound is indicated to determine whether there is evidence of mechanical obstruction and dilatation of the biliary tree (Fig. 22.15). EUS provides an additional investigation modality for investigation of lower common bile duct obstruction.

Management of cholestatic jaundice depends on the underlying cause and is discussed in the relevant sections below.

Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour

*Each of these diseases can give rise to almost any of the clinical features shown but the box indicates the most likely cause of the clinical features listed.

Hepatomegaly

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (>1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill/fluid wave. Other features include evasion of the umbilicus, herniae, abdominal striae, diavariation of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

Pathophysiology

Ascites has numerous causes, the most common of which are malignant disease, cirrhosis and heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease (Box 22.21). Splanchnic vasodilatation is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic vasodilatation as cirrhosis advances. This leads to activation of the renin–angiotensin system with secondary aldosteronism, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity

*Meigs’ syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour.

(SAAG = serum ascites albumin gradient; see text)
outflow obstruction can also cause a transudative ascites, as outflow obstruction due to cardiac failure or hepatic venous pressure must be avoided (Box 22.23). Restriction of water intake to 1.0–1.5 L/24 hrs is necessary only if the plasma sodium falls below 125 mmol/L. Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid and electrolyte balance, and precipitate hepatic encephalopathy (p. 864). Treatment of transudative ascites is based on restricting sodium and water intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy is treated with paracentesis but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid daily, so body weight should not fall by more than 1 kg daily to avoid excessive fluid depletion.

Sodium and water restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/24 hrs (‘no added salt diet’) is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 22.23). Restriction of water intake to 1.0–1.5 L/24 hrs is necessary only if the plasma sodium falls below 125 mmol/L.

Investigations

Ultrasoundography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can be used to obtain ascitic fluid for analysis. The appearance of ascites fluid may point to the underlying cause (Box 22.22). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and identified only on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the protein concentration and the serum–ascites albumin gradient (SAAG) can be a useful tool to distinguish ascites of different aetiologies. Cirrhotic patients typically develop ascites with a low protein concentration (‘transudate’; protein concentration <25 g/L (2.5 g/dL) and relatively few cells. In up to 30% of patients, however, the total protein concentration is >30 g/L (3.0 g/dL). In these cases, it is useful to calculate the SAAG by subtracting the concentration of the ascites fluid albumin from the serum albumin. A gradient of >11 g/L (1.1 g/dL) is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a transudative ascites, as indicated by an albumin gradient of >11 g/L (1.1 g/dL) but, unlike in cirrhosis, the total protein content is usually >25 g/L (2.5 g/dL).

High protein ascites (‘exudate’; protein concentration >25 g/L (2.5 g/dL) or a SAAG of <11 g/L (1.1 g/dL) raises the possibility of infection (especially tuberculosis), malignancy, pancreatic ascites or, rarely, hypothyroidism. Ascites amylase activity of >1000 U/L identifies pancreatic ascites, whereas low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells (one-third of cirrhotic patients with a bloody tap have a hepatocellular carcinoma). Polymorphonuclear leucocyte counts of >250 ×10⁶/L strongly suggest infection (spontaneous bacterial peritonitis; see below). Laparoscopy can be valuable in detecting peritoneal disease.

The presence of triglyceride at a level >1.1 g/L (110 mg/dL) is diagnostic of chylous ascites and suggests anatomical or functional abnormality of lymphatic drainage from the abdomen. The ascites in this context has a characteristic milky-white appearance.

Management

Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid and electrolyte balance, and precipitate hepatic encephalopathy (p. 864). Treatment of transudative ascites is based on restricting sodium and water intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy is treated with paracentesis but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid daily, so body weight should not fall by more than 1 kg daily to avoid excessive fluid depletion.

Sodium and water restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/24 hrs (‘no added salt diet’) is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 22.23). Restriction of water intake to 1.0–1.5 L/24 hrs is necessary only if the plasma sodium falls below 125 mmol/L.

![Pathogenesis of ascites.](Image)
Diuretics
Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the first-line drug because it is a powerful aldosterone antagonist; it can, however, cause painful gynaecomastia and hyperkalaemia, in which case amiloride (5–10 mg/day) can be substituted. Some patients also require loop diuretics, such as furosemide, but these can lead to fluid and electrolyte imbalance and renal dysfunction. Diuresis may be improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to doses of 400 mg spironolactone and 160 mg furosemide, or who are unable to tolerate these doses due to hyponatraemia or renal impairment, are considered to have refractory or diuretic-resistant ascites and should be treated by other measures.

Paracentesis
First-line treatment of refractory ascites is large-volume paracentesis. Paracentesis to dryness is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% or 25% human albumin solution (HAS) for every 1.5–2 L of ascites drained) or another plasma expander. Paracentesis can be used as an initial therapy or when other treatments fail.

Transjugular intrahepatic portosystemic stent shunt
A transjugular intrahepatic portosystemic stent shunt (TIPSS; p. 870) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. TIPSS can be used in patients awaiting liver transplantation or in those with reasonable liver function, but can aggravate encephalopathy in those with poor function.

Complications
Renal failure
Renal failure can occur in patients with ascites. It can be pre-renal and due to vasodilatation from sepsis and/or diuretic therapy, or due to hepatorenal syndrome.

Hepatorenal syndrome
This occurs in 10% of patients with advanced cirrhosis complicated by ascites. There are two clinical types; both are mediated by renal vasoconstriction due to under-filling of the arterial circulation.

Type 1 hepatorenal syndrome
This is characterised by progressive oliguria, a rapid rise of the serum creatinine and a very poor prognosis (without treatment, median survival is less than 1 month). There is usually no proteinuria, a urine sodium excretion of less than 10 mmol/24 hrs and a urine/plasma osmolality ratio of more than 1.5. Other non-functional causes of renal failure must be excluded before the diagnosis is made. Treatment consists of albumin infusions in combination with terlipressin (or octreotide and midodrine where terlipressin is not approved for use) and is effective in about two-thirds of patients. Haemodialysis should not be used routinely because it does not improve the outcome. Patients who survive should be considered for liver transplantation, which, along with TIPSS, is an effective treatment in appropriate patients.

Type 2 hepatorenal syndrome
This usually occurs in patients with refractory ascites, is characterised by a moderate and stable increase in serum creatinine, and has a better prognosis.

Spontaneous bacterial peritonitis
Spontaneous bacterial peritonitis (SBP) may present with abdominal pain, rebound tenderness, absent bowel sounds and fever in a patient with obvious features of cirrhosis and ascites. Abdominal signs are mild or absent in about one-third of patients, and in these individuals hepatic encephalopathy and fever are the main features. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count of >250×106/L almost invariably indicates infection. The source of infection cannot usually be determined, but most organisms isolated are of enteric origin and Escherichia coli is the most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime or piperacillin/tazobactam. Recurrence of SBP is common but may be reduced with prophylactic quinolones, such as norfloxacin or ciprofloxacin. Prophylactic antibiotics reduce the incidence of SBP and improve survival in cirrhotic patients with gastrointestinal bleeding. In patients with a previous episode of SBP and continued ascites, norfloxacin (400 mg/day) prevents recurrence.

Prognosis
Only 10–20% of patients survive for 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.

Hepatic encephalopathy
Hepatic encephalopathy is a neuropsychiatric syndrome caused by liver disease. As it progresses, delirium is followed by coma. Simple delirium needs to be differentiated from delirium tremens and Wernicke’s encephalopathy, and coma from subdural haematoma, which can occur in alcoholics after a fall (Box 22.24). Features include changes of intellect, personality, emotions and consciousness, with or without neurological signs. The degree of encephalopathy can be graded from 1 to 4, depending on these features, and this is useful in assessing response to therapy (see Box 22.9). When an episode develops acutely, a precipitating factor may be found (Box 22.25). The earliest features are very
mild and easily overlooked, but as the condition becomes more severe, apathy, inability to concentrate, delirium, disorientation, drowsiness, slurring of speech and eventually coma develop. Convulsions sometimes occur. Examination usually shows a flapping tremor (asterixis), inability to perform simple mental arithmetic tasks or to draw objects such as a star (constructional apraxia; p. 847), and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs; if these are present, other causes must be sought. Fetor hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating neurotoxins that are normally metabolised by the liver. Accordingly, most affected patients have evidence of liver failure and portosystemic shunting of blood, but the balance between these varies from individual to individual.

Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. The ‘neurotoxins’ causing encephalopathy are unknown but are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. These substances are normally metabolised by the healthy liver and excluded from the systemic circulation. Ammonia has traditionally been considered an important factor. Recent interest has focused on γ-aminobutyric acid (GABA) as a mediator, along with octopamine, amino acids, mercaptans and fatty acids that can act as neurotransmitters. The brain in cirrhosis may also be sensitised to other factors, such as drugs that can precipitate hepatic encephalopathy (Box 22.25). Disruption of the function of the blood–brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

Investigations

The diagnosis can usually be made clinically; when doubt exists, an electroencephalogram shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. Increased concentrations can, however, occur in the absence of clinical encephalopathy, rendering this investigation of little diagnostic value.

Management

The principles are to treat or remove precipitating causes (Box 22.25) and to suppress the production of neurotoxins by bacteria in the bowel. Dietary protein restriction is rarely needed and is no longer recommended as first-line treatment because it is unpalatable and can lead to a worsening nutritional state in already malnourished patients. Lactulose (15–30 mL 3 times daily) is increased gradually until the bowels are moving twice daily. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Rifaximin (400 mg 3 times daily) is a well-tolerated, non-absorbed antibiotic that acts by reducing the bacterial content of the bowel and has been shown to be effective. It can be used in addition, or as an alternative, to lactulose if diarrhoea becomes troublesome. Chronic or refractory encephalopathy is one of the main indications for liver transplantation.

Variceal bleeding

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices (Fig. 22.17) is common in chronic liver disease. Investigation

---

**Fig. 22.17** Varices: endoscopic views. (A) Oesophageal varices (arrows) at the lower end of the oesophagus. (B) Gastric varices (arrows). (C) Appearance of oesophageal varices following application of strangulating bands (band ligation, arrow).
Cirrhosis is characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. It is the most common cause of portal hypertension and its complications. Worldwide, the most common causes are chronic viral hepatitis, prolonged excessive alcohol consumption and NAFLD but any condition leading to persistent or recurrent hepatocyte death may lead to cirrhosis. The causes of cirrhosis are listed in Box 22.26.

Cirrhosis may also occur in prolonged biliary damage or obstruction, as is found in primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC) and post-surgical biliary strictures. Persistent blockage of venous return from the liver, such as is found in sinusoidal obstruction syndrome (SOS; veno-occlusive disease) and Budd–Chiari syndrome, can also result in cirrhosis.

Pathophysiology
Following liver injury, stellate cells in the space of Disse (see Fig. 22.3, p. 849) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and other mediators that promote hepatocyte damage and tissue fibrosis (see Fig. 22.4, p. 849).

Cirrhosis is a histological diagnosis (Fig. 22.18). It evolves over years as progressive fibrosis and widespread hepatocyte loss lead to distortion of the normal liver architecture that disrupts the hepatic vasculature, causing portosystemic shunts. These changes usually affect the whole liver but in biliary cirrhosis (e.g. PBC) they can be patchy. Cirrhosis can be classified histologically into:

- **Micronodular cirrhosis**, characterised by small nodules about 1 mm in diameter and typically seen in alcoholic cirrhosis.
- **Macronodular cirrhosis**, characterised by larger nodules of various sizes. Areas of previous collapse of the liver architecture are evidenced by large fibrous scars.

Clinical features
The clinical presentation is highly variable. Some patients are asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly, signs of portal hypertension (p. 868) or hepatic insufficiency. When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea, vomiting and upper abdominal discomfort (Box 22.27). Cirrhosis will occasionally present because of shortness of breath due to a large right pleural effusion, or with hepatopulmonary syndrome (p. 898).

Hepatomegaly is common when the cirrhosis is due to alcoholic liver disease or haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. A reduction in liver size is especially common if the cause is viral hepatitis or autoimmune liver disease. The liver is often hard, irregular and non-tender. Jaundice is mild when it first appears and is due primarily to a failure to excrete bilirubin. Palmar erythema

---

**22.26 Causes of cirrhosis**

- Alcohol
- Chronic viral hepatitis (B or C)
- Non-alcoholic fatty liver disease
- Immune:
  - Primary sclerosing cholangitis
  - Autoimmune liver disease
- Biliary:
  - Primary biliary cholangitis
  - Secondary biliary cirrhosis
  - Cystic fibrosis
- Genetic:
  - Haemochromatosis
  - Wilson’s disease
  - α1-antitrypsin deficiency
- Cryptogenic (unknown – 15%)
- Chronic venous outflow obstruction
- Any chronic liver disease

**Fig. 22.18** Histological features in normal liver, hepatic fibrosis and cirrhosis. A Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intrahepatic bile duct branch of the hepatic artery and portal venous radicular. B Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular) and linking adjacent portal tracts and hepatic veins. C A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).
Hepatomegaly (although liver may also be small)
Jaundice
Ascites
Circulatory changes: spider telangiectasia, palmar erythema, cyanosis
Endocrine changes: loss of libido, hair loss
  Men: gynaecomastia, testicular atrophy, impotence
  Women: breast atrophy, irregular menses, amenorrhoea
Haemorrhagic tendency: bruises, purpura, epistaxis
Portal hypertension: splenomegaly, collateral vessels, variceal bleeding
Hepatic (porto-systemic) encephalopathy
Other features: pigmentation, digital clubbing, Dupuytren’s contracture

Encephalopathy
Variceal bleeding
Hepatic encephalopathy
Ascites:
  Spontaneous bacterial peritonitis
  Hepatorenal failure

Worsening synthetic liver function:
  Prolonged prothrombin time
  Low albumin
Jaundice
Portal hypertension

Score: None Mild Marked
Encephalopathy
Bilirubin (μmol/L (mg/dL))
  Primary biliary cholangitis/sclerosing cholangitis
  Other causes of cirrhosis
  Albumin (g/L (g/dL))
Prothrombin time (secs prolonged)
Ascites

Add the individual scores:
  \(< 7 = \text{Child’s A}, 7–9 = \text{Child’s B}, 9 = \text{Child’s C}\)

*To convert bilirubin in μmol/L to mg/dL, divide by 17.

Management
This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications, including ascites, hepatic encephalopathy, portal hypertension and varicos. Once the diagnosis of cirrhosis is made, endoscopy should be performed
can be seen early in the disease but is of limited diagnostic value, as it occurs in many other conditions associated with a hyperdynamic circulation, including normal pregnancy, as well as being found in some healthy people. Spider telangiectasias occur and comprise a central arteriole (that occasionally raises the skin surface), from which small vessels radiate. They vary in size from 1 to 2 mm in diameter and are usually found only above the nipples. One or two small spider telangiectasias may be present in about 2% of healthy people and may occur transiently in greater numbers in the third trimester of pregnancy, but otherwise they are a strong indicator of liver disease. Florid spider telangiectasia, gynaecomastia and parotid enlargement are most common in alcoholic cirrhosis. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Pulmonary arteriovenous shunts also develop, leading to hypoxaemia and eventually to central cyanosis, but this is a late feature.

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances.

Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below). Ascites also signifies advanced disease. Evidence of hepatic encephalopathy also becomes common with disease progression. Non-specific features of chronic liver disease include clubbing of the fingers and toes. Dupuytren’s contracture is traditionally regarded as a complication of cirrhosis but the evidence for this is weak. Chronic liver failure develops when the metabolic capacity of the liver is exceeded. It is characterised by the presence of encephalopathy and/or ascites. The term ‘hepatic decompensation’ or ‘decompensated liver disease’ is often used when chronic liver failure occurs.

Other clinical and laboratory features may be present (Box 22.28); these include peripheral oedema, renal failure, jaundice, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis.

Prognosis
The overall prognosis is poor. Many patients present with advanced disease and/or serious complications that carry a high mortality. Overall, only 25% of patients survive 5 years from diagnosis, but where liver function is good, 50% survive for 5 years and 25% for up to 10 years. The prognosis is more favourable when the underlying cause can be corrected, as in alcoholic misuse, haemochromatosis or Wilson’s disease.

Laboratory tests give only a rough guide to prognosis in individual patients. Deteriorating liver function, as evidenced by jaundice, ascites or encephalopathy, indicates a poor prognosis unless a treatable cause such as infection is found. Increasing bilirubin, falling albumin (or an albumin concentration of <30 g/L (3.0 g/dL)), marked hyponatraemia (<120 mmol/L) not due to diuretic therapy, and a prolonged PT are all bad prognostic features (Box 22.29 and Fig. 22.19). The Child–Pugh and MELD (Model for End-stage Liver Disease) scores can be used to assess prognosis. The MELD is more difficult to calculate at the bedside but, unlike the Child–Pugh score, includes renal function; if this is impaired, it is known to be a poor prognostic feature in end-stage disease (Box 22.30). Although these scores give a guide to prognosis, the course of cirrhosis can be unpredictable, as complications such as variceal bleeding may occur.
more than 5 cm below the left costal margin in adults but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a 'caput medusae' (p. 846). Rarely, a large umbilical collateral vessel has a blood flow sufficient to give a venous hum on auscultation (Cruveilhier–Baumgarten syndrome). The most important collateral vessel formation occurs in the oesophagus and stomach, and this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids (which are no more common in portal hypertension than in the general population). Fetor hepaticus results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

**Clinical features**

The clinical features result principally from portal venous congestion and collateral vessel formation (Box 22.31). Splenomegaly is a cardinal finding and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged
Ascites occurs as a result of renal sodium retention and portal hypertension that may be due, for example, to post-hepatic causes (hepatic outflow obstruction, p. 862) or cirrhosis.

The most important consequence of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the gastro-oesophageal junction, or from gastric varices. The size of the varices, endoscopic variceal features such as red spots and stripes, high portal pressure and liver failure are all general factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates and NSAIDs, can also precipitate bleeding. Variceal bleeding is often severe, and recurrent if preventative treatment is not given.

Pathophysiology

Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels, allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, ilar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. As collateral vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

Investigations

The diagnosis is often made clinically. Portal venous pressure measurements are rarely needed for clinical assessment or routine management but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements are made by using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the WHVP. This is an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of $100 \times 10^9/L$; values below $50 \times 10^9/L$ are uncommon. Leucopenia occurs occasionally but anaemia is seldom attributed directly to hypersplenism; if anaemia is found, a source of bleeding should be sought.

Endoscopy is the most useful investigation to determine whether gastro-oesophageal varices are present (see Fig. 22.17). Once the diagnosis of cirrhosis is made, endoscopy should be performed to screen for oesophageal varices (and repeated every 2 years). Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as liver disease or portal vein thrombosis. CT and magnetic resonance angiography can identify the extent of portal vein clot and are used to identify hepatic vein patency.

Management

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices is a common manifestation of chronic liver disease. In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but is still about 45% in those with poor liver function (i.e. Child–Pugh C).

The management of portal hypertension is largely focused on the prevention and/or control of variceal haemorrhage. It is important to remember, though, that bleeding can also result from peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail on page 780.

Primary prevention of variceal bleeding

If non-bleeding varices are identified at endoscopy, $\beta$-adrenoceptor antagonist ($\beta$-blocker) therapy with propranolol ($80–160$ mg/day) or nadolol ($40–240$ mg/day) is effective in reducing portal venous pressure. Administration of these drugs at doses that reduce the heart rate by 25% has been shown to be effective in the primary prevention of variceal bleeding. In patients with cirrhosis, treatment with propranolol reduces variceal bleeding by 47% (number needed to treat for benefit (NNT$\beta$ 10), death from bleeding by 45% (NNT$\beta$ 25) and overall mortality by 22% (NNT$\beta$ 16). The efficacy of $\beta$-blockers in primary prevention is similar to that of prophylactic banding, which may also be considered, particularly in patients who are unable to tolerate or adhere to $\beta$-blocker therapy. Carvedilol, a non-cardioselective vasodilating $\beta$-blocker, is also effective and may be better tolerated at doses of 6.25–12.5 mg/day). For these, dose should be titrated, as tolerated, to achieve a heart rate of 50–55 beats/min, if possible.

Management of acute variceal bleeding

The priority in acute bleeding is to restore the circulation with blood and plasma, not least because shock reduces liver blood flow and causes further deterioration of liver function. The source of bleeding should always be confirmed by endoscopy because about 20% of patients are bleeding from non-variceal lesions. Management of acute variceal bleeding is described in Box 22.32 and illustrated in Figure 22.21. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as oral ciprofloxacin or intravenous cephalosporin or piperacillin/tazobactam, because sepsis is common and treatment with antibiotics improves outcomes. The measures used to control acute variceal bleeding include vasoactive medications (e.g. terlipressin), endoscopic therapy (banding or sclerotherapy), balloon tamponade, TIPSS and, rarely, oesophageal transection.

### 22.32 Emergency management of bleeding

*Caution in patients with significant coronary artery, peripheral or other vascular disease.
Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than sclerotherapy, a technique in which varices are injected with a sclerosing agent, and has largely replaced it. Banding is best suited to the treatment of oesophageal varices. It is associated with a lower risk of oesophageal perforation or stricturing than sclerotherapy. Prophylactic acid suppression with proton pump inhibitors reduces the risk of secondary bleeding from banding-induced ulceration.

In the case of gastric fundal varices, banding is less effective and so endoscopic therapy relies on injection of agents such as thrombin or cyanoacrylate glue directly into the varix to induce thrombosis. Although highly effective, cyanoacrylate injection treatment may be complicated by ‘glue embolism’ to the lungs. Active bleeding may make endoscopic therapy difficult. Protection of the patient’s airway with endotracheal intubation aids the endoscopist, facilitating therapy and significantly reducing the risk of pulmonary aspiration.

Balloon tamponade This technique employs a Sengstaken–Blakemore tube, which consists of two balloons that exert pressure in the fundus of the stomach and in the lower oesophagus, respectively (Fig. 22.22). Additional lumens allow contents to be aspirated from the stomach and from the oesophagus above the oesophageal balloon. This technique may be used in the event of life-threatening haemorrhage if early endoscopic therapy is not available or is unsuccessful.

Endotracheal intubation prior to tube insertion reduces the risk of pulmonary aspiration. The tube should be passed through the mouth and its presence in the stomach should be checked by auscultating the upper abdomen while injecting air and by confirming with radiology. The safest technique is

Pharmacological reduction of portal venous pressure Terlipressin is a synthetic vasopressin analogue that, in contrast to vasopressin, can be given by intermittent injection rather than continuous infusion. It reduces portal blood flow and/or intrahepatic resistance and hence brings down portal pressure. It lowers mortality in the setting of acute variceal bleeding. The dose of terlipressin is 2 mg IV 4 times daily until bleeding stops, and then 1 mg 4 times daily for up to 72 hours. Caution is needed in patients with severe ischaemic heart disease or peripheral vascular disease because of the drug’s vasoconstrictor properties. In countries where terlipressin is not available, octreotide is a frequently used alternative.

Variceal ligation (‘banding’) and sclerotherapy This is the most widely used initial treatment and is undertaken, if possible, at the time of diagnostic endoscopy (see Fig. 22.17C). It stops variceal bleeding in 80% of patients and can be repeated if bleeding recurs. Band ligation involves the varices being sucked into a cap placed on the end of the endoscope, allowing them to be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 2–4 weeks until all varices are obliterated.

**Fig. 22.21** Management of acute bleeding from oesophageal varices. (TIPSS = transjugular intrahepatic portosystemic stent shunt)

**Fig. 22.22** Sengstaken–Blakemore tube.
to inflate the balloon in the stomach under direct endoscopic vision. Gentle traction is essential to maintain pressure on the varices. Initially, only the gastric balloon should be inflated, with 200–250 mL of air, as this will usually control bleeding. Inflation of the gastric balloon must be stopped if the patient experiences pain because inadvertent inflation in the oesophagus can cause oesophageal rupture. If the oesophageal balloon needs to be used because of continued bleeding, it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Pressure in the oesophageal balloon should be monitored with a sphygmomanometer and should not exceed 40 mmHg. Balloon tamponade will almost always stop oesophageal and gastric fundal variceal bleeding but is only a bridge to more definitive therapy. Self-expanding removable oesophageal stents are a new alternative in patients with bleeding oesophageal, but not gastric, varices.

**TIPSS** This technique uses a stent placed between the portal vein and the hepatic vein within the liver to provide a portosystemic shunt and therefore reduce portal pressure (Fig. 22.23). It is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically, coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents further variceal bleeding, and is an effective treatment for both oesophageal and gastric varices. Further bleeding necessitates investigation and treatment (e.g. angioembolisation) because it is usually associated with shunt narrowing or occlusion. Hepatic encephalopathy may occur following TIPSS and is managed by reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved.

**Portosystemic shunt surgery** Surgery prevents recurrent bleeding but carries a high mortality and often leads to encephalopathy. In practice, portosystemic shunts are now reserved for when other treatments have not been successful and are offered only to patients with good liver function.

**Oesophageal transection** Rarely, surgical transection of the varices may be performed as a last resort when bleeding cannot be controlled by other means but operative mortality is high.

**Secondary prevention of variceal bleeding** Beta-blockers are used as a secondary measure to prevent recurrent variceal bleeding. Following successful endoscopic therapy, patients should be entered into an oesophageal banding programme with repeated sessions of therapy at 12–24-week intervals until the varices are obliterated. In selected individuals, TIPSS may also be considered in this setting.

### Congestive ‘portal hypertensive’ gastropathy

Long-standing portal hypertension causes chronic gastric congestion, which is recognisable at endoscopy as multiple areas of punctate erythema (‘portal hypertensive gastropathy’ or ‘snakeskin gastropathy’). Rarely, similar lesions occur more distally in the gastrointestinal tract. These areas may become eroded, causing bleeding from multiple sites. Acute bleeding can occur but repeated minor bleeding causing iron deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using propranolol (80–160 mg/day) is the best initial treatment. If this is ineffective, a TIPSS procedure can be undertaken.

### Infections and the liver

The liver may be subject to a number of different infections. These include hepatotropic viral infections and bacterial and protozoal infections. Each has specific clinical features and requires targeted therapies.

**Viral hepatitis**

This must be considered in anyone presenting with hepatic liver blood tests (high transaminases). The causes are listed in Box 22.33.

All these viruses cause illnesses that have similar clinical and pathological features and are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in Box 22.34. Therapeutic developments for viral hepatitis, in particular hepatitis C, are evolving very rapidly, with several new classes of drugs entering clinical practice.

**Clinical features of acute infection**

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow and abdominal discomfort is common.

**Fig. 22.23** Transjugular intrahepatic portosystemic stent shunt (TIPSS). X-ray showing placement of a TIPSS within the portal vein (PV), allowing blood to flow from the portal vein into the hepatic vein (HV) and then the inferior vena cava (IVC).
The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal–oral route. Infected individuals, who may be asymptomatic, excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and then for a further 2 weeks or so. Infection is common in children but often asymptomatic, and so up to 30% of adults will have serological evidence of past infection but give no history of jaundice. Infection is also more common in areas of overcrowding and poor sanitation. In occasional outbreaks, water and shellfish have been the vehicles of transmission. In contrast to hepatitis B, a chronic carrier state does not occur.

**Investigations**

Only one HAV antigen has been found and infected people make an antibody to this antigen (anti-HAV). Anti-HAV is important in diagnosis, as HAV is present in the blood only transiently during the incubation period. Excretion in the stools occurs for only 7–14 days after the onset of the clinical illness and the virus cannot be grown readily. Anti-HAV of the IgM type, indicating a primary immune response, is already present in the blood at the onset of the clinical illness and is diagnostic of an acute HAV infection. Titres of this antibody fall to low levels within about 3 months of recovery. Anti-HAV of the IgG type is of no diagnostic value, as HAV infection is common and this antibody persists for years after infection, but it can be used as a marker of previous HAV infection. Its presence indicates immunity to HAV.

**Management**

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated virus vaccine. Immunisation should be considered for individuals with chronic hepatitis B or C infections. Immediate protection can be provided by immune serum globulin if this is given soon after exposure to the virus. The protective effect of immune serum globulin is attributed to its anti-HAV content. Immunisation should be
considered for those at particular risk, such as close contacts of HAV-infected patients, the elderly, those with other major disease and perhaps pregnant women.

Immune serum globulin can be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families. People travelling to endemic areas are best protected by vaccination.

Acute liver failure is rare in hepatitis A (0.1%) and chronic infection does not occur. Infection in patients with chronic liver disease, however, may cause serious or life-threatening disease. In adults, a cholestatic phase with elevated ALP levels may complicate infection. There is no role for antiviral drugs in the therapy of HAV infection.

## Hepatitis B

The hepatitis B virus consists of a core containing DNA and a DNA polymerase enzyme needed for virus replication. The core of the virus is surrounded by surface protein (Fig. 22.24). The virus, also called a Dane particle, and an excess of its surface protein (known as hepatitis B surface antigen, HBsAg) circulate in the blood. Humans are the only source of infection.

Hepatitis B is one of the most common causes of chronic liver disease and hepatocellular carcinoma worldwide. Approximately one-third of the world’s population have serological evidence of past or current infection with hepatitis B and approximately 350–400 million people are chronic HBsAg carriers.

Hepatitis B may cause an acute viral hepatitis; however, acute infection is often asymptomatic, particularly when acquired at birth. Many individuals with chronic hepatitis B are also asymptomatic.

The risk of progression to chronic liver disease depends on the source and timing of infection (Box 22.36). Vertical transmission from mother to child in the perinatal period is the most common cause of infection worldwide and carries the highest risk of ongoing chronic infection. In this setting, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Several mechanisms contribute towards this:

- Firstly, the introduction of antigen in the neonatal period is tolerogenic.
- Secondly, the presentation of such antigen within the liver, as described above, promotes tolerance; this is particularly evident in the absence of a significant innate or inflammatory response.

Finally, very high loads of antigen may lead to so-called ‘exhaustion’ of cellular immune responses. The state of tolerance is not permanent, however, and may be reversed as a result of therapy, or through spontaneous changes in innate responses, such as interferon alpha (IFN-α) and NK cells, accompanied by host-mediated immunopathology.

Chronic hepatitis can lead to cirrhosis or hepatocellular carcinoma, usually after decades of infection (Fig. 22.25). Chronic HBV infection is a dynamic process that can be divided into five phases (Box 22.37); these are not necessarily sequential, however, and not all patients will go through all phases. It is important to remember that the virus is not directly cytotoxic to cells; rather, it is an immune response to viral antigens displayed on infected hepatocytes that initiates liver injury. This explains why there may be very high levels of viral replication but little hepatocellular damage during the ‘immune-tolerant’ phase.

### Investigations

#### Serology

HBV contains several antigens to which infected persons can make immune responses (Fig. 22.26); these antigens and their antibodies are important in identifying HBV infection (Boxes 22.37 and 22.38), although the widespread availability of polymerase chain reaction (PCR) techniques to measure viral DNA levels in peripheral blood means that longitudinal monitoring is now also frequently guided by direct assessment of viral load.

**Hepatitis B surface antigen** Hepatitis B surface antigen (HBsAg) is an indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. In acute liver failure from hepatitis B, the liver damage is mediated by viral clearance and not HBsAg; rather, it is an immune response to viral antigens displayed on infected hepatocytes that initiates liver injury. This explains why there may be very high levels of viral replication but little hepatocellular damage during the ‘immune-tolerant’ phase.

**Hepatitis B core antigen** Hepatitis B core antigen (HBcAg) is not found in the blood, but antibody to it (anti-HBc) appears early

### Horizontal transmission (10%)

- Injection drug use
- Infected unscreened blood products
- Tattoos/acupuncture needles
- Sexual transmission
- Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)

### Vertical transmission (90%)

- Hepatitis B surface antigen (HBsAg)-positive mother

---

**Fig. 22.24 Schematic diagram of the hepatitis B virus.** Hepatitis B surface antigen (HBsAg) is a protein that makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein that makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg that can be found in the blood and indicates infectivity.
Hepatitis B e antigen (HBeAg) is an indicator of viral replication. In acute hepatitis B it may appear only transiently at the outset of the illness; its appearance is followed by the production of antibody (anti-HBe). The HBeAg reflects active replication of the virus in the liver. In the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type, with IgG antibody appearing later. Anti-HBc (IgM) can sometimes reveal an acute HBV infection when the HBsAg has disappeared and before anti-HBs has developed (see Fig. 22.26 and Box 22.38).

Hepatitis B e antigen Hepatitis B e antigen (HBeAg) is an indicator of viral replication. In acute hepatitis B it may appear only transiently at the outset of the illness; its appearance is followed by the production of antibody (anti-HBe). The HBeAg reflects active replication of the virus in the liver.

---

**Fig. 22.25 Natural history of chronic hepatitis B virus (HBV) infection.** There is an initial immunotolerant phase with high levels of virus and normal liver biochemistry. An immunological response to the virus then occurs, with elevation in serum transaminases, which causes liver damage: chronic hepatitis. If this response is sustained over many years and viral clearance does not occur promptly, chronic hepatitis may result in cirrhosis. In individuals with a successful immunological response, viral load falls, HBe antibody (HBeAg) develops and there is no further liver damage. Some individuals may subsequently develop HBV-DNA mutants that escape from immune regulation, and viral load again rises with further chronic hepatitis. Mutations in the core protein result in the virus’s inability to secrete HBe antigen despite high levels of viral replication; such individuals have HBeAg-negative chronic hepatitis. (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

(HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HCC = hepatocellular carcinoma)
Viral load and genotype

HBV-DNA can be measured by PCR in the blood. Viral loads are usually in excess of $10^5$ copies/mL in the presence of active viral replication, as indicated by the presence of e antigen. In contrast, in individuals with low viral replication, who are HBsAg- and anti-HBe-negative, viral loads are less than $10^5$ copies/mL. The exception is in patients who have a mutation in the pre-core protein, which means they cannot secrete e antigen into serum (Fig. 22.27). Such individuals will be anti-HBe-positive but have a high viral load and often evidence of chronic hepatitis. These mutations are common in the Far East, and those patients affected are classified as having e antigen-negative chronic hepatitis. They respond differently to antiviral drugs from those with classical e antigen-positive chronic hepatitis.

Measurement of viral load is important in monitoring antiviral therapy and identifying patients with pre-core mutants. Specific HBV genotypes (A–H) can also be identified using PCR. In some settings, these may be useful in guiding therapy, as genotype A tends to respond better to pegylated interferon-alfa compared to genotypes C and D.

Management of acute hepatitis B

Treatment is supportive with monitoring for acute liver failure, which occurs in less than 1% of cases. There is no definitive evidence that antiviral therapy reduces the severity or duration of acute hepatitis B.

Full recovery occurs in 90–95% of adults following acute HBV infection. The remaining 5–10% develop a chronic hepatitis B infection that usually continues for life, although later recovery occasionally occurs. Infection passing from mother to child at birth leads to chronic infection in the child in 90% of cases and recovery is rare. Chronic infection is also common in immunodeficient individuals, such as those with Down’s syndrome or human immunodeficiency virus (HIV) infection. Fulminant liver failure due to acute hepatitis B occurs in less than 1% of cases. There is no definitive treatment with lamivudine.

Management of chronic hepatitis B

Treatments are still limited, as no drug is consistently able to eradicate hepatitis B infection completely (i.e. render the
patient HBsAg-negative). The goals of treatment are HBeAg seroconversion, reduction in HBV-DNA and normalisation of the LFTs. The indication for treatment is a high viral load in the presence of active hepatitis, as demonstrated by elevated serum transaminases and/or histological evidence of inflammation and fibrosis. The oral antiviral agents are more effective in reducing viral loads in patients with e antigen-negative chronic hepatitis B than in those with e antigen-positive chronic hepatitis B, as the pre-treatment viral loads are lower.

Most patients with chronic hepatitis B are asymptomatic and develop complications, such as cirrhosis and hepatocellular carcinoma, only after many years (see Fig. 22.25). Cirrhosis develops in 15–20% of patients with chronic HBV over 5–20 years. This proportion is higher in those who are e antigen-negative.

Two different types of drug are used to treat hepatitis B: direct-acting nucleoside/nucleotide analogues and pegylated interferon-alfa.

Direct-acting nucleoside/nucleotide antiviral agents
Orally administered nucleoside/nucleotide antiviral agents are the mainstay of therapy. These act by inhibiting the reverse transcription of pre-genomic RNA to HBV-DNA by HBV-DNA polymerase but do not directly affect the covalently closed circular DNA (cccDNA) template for viral replication, and so relapse is common if treatment is withdrawn. One major concern is the selection of antiviral-resistant mutations with long-term treatment. This is particularly important with some of the older agents, such as lamivudine, as mutations induced by previous antiviral exposure may also induce resistance to newer agents. Entecavir and tenofovir (see below) are potent antivirals with a high barrier to genetic resistance and so are the most appropriate first-line agents.

Lamivudine Although effective, long-term therapy is often complicated by the development of HBV-DNA polymerase mutants (e.g. the "YMDD variant"), which lead to viral resistance. These occur after approximately 9 months and are characterised by a rise in viral load during treatment. Outside resource-limited settings, this agent is now seldom used for the treatment of HBV but may be used to prevent reactivation of HBV in previously infected, HBsAg-negative patients if they are undergoing chemotherapy.

Entecavir and tenofovir Monotherapy with entecavir or tenofovir is substantially more effective than lamivudine in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis. Antiviral resistance mutations occur in only 1–2% after 3 years of entecavir drug exposure. Both drugs have anti-HIV action and so their use as monotherapy is contraindicated in HIV-positive patients, as it may lead to HIV antiviral drug resistance. Current European guidelines advise that the other nucleoside/nucleotide antivirals should not be used as first-line monotherapy due to the induction of viral mutations, unless more potent drugs with a high barrier to resistance are not available or appropriate.

Interferon-alfa
This is most effective in patients with a low viral load and serum transaminases greater than twice the upper limit of normal, in whom it acts by augmenting a native immune response. In HBeAg-positive chronic hepatitis, 33% lose e antigen after 4–6 months of treatment, compared to 12% of controls. Response rates are lower in HBeAg-negative chronic hepatitis, even when patients are given longer courses of treatment. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. Longer-acting pegylated interferons that can be given once weekly have been evaluated in both HBeAg-positive and HBeAg-negative chronic hepatitis. Side-effects are common and include fatigue, depression, irritability, bone marrow suppression and the triggering of autoimmune thyroid disease.

Liver transplantation
Historically, liver transplantation was contraindicated in hepatitis B because infection often recurred in the graft. The use of post-liver transplant prophylaxis with direct-acting antiviral agents and hepatitis B immunoglobulins has, however, reduced the reinfection rate to 10% and increased 5-year survival to 80%, making transplantation an acceptable treatment option.

Prevention
Individuals are most infectious when markers of continuing viral replication, such as HBeAg, and high levels of HBV-DNA are present in the blood. HBV-DNA can be found in saliva, urine, semen and vaginal secretions (although urine is not usually considered to be capable of transmitting infection). The virus is about ten times more infectious than hepatitis C, which in turn is about ten times more infectious than HIV.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active immunisation in 95% of normal individuals. The vaccine should be offered to those at special risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 22.39). The vaccine is ineffective in those already infected by HBV. Infection can also be prevented or minimised by the intramuscular injection of specific hepatitis B immunoglobulin (HB Ig) prepared from blood containing anti-HBs. This should be given within 48 hours, or at most a week, of exposure to infected blood in circumstances likely to cause infection (e.g. needlestick injury, contamination of cuts or mucous membranes). Vaccine can be given together with HB Ig (active–passive immunisation).

Neonates born to hepatitis B-infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

Co-infection with HIV
Around 10% of the HIV-infected population has concurrent HBV and this figure may be as high as 25% in areas where both viruses are prevalent. Up to half of injection drug users with HIV are co-infected with HBV. Co-infection increases the morbidity and mortality compared to either infection alone: there are greater levels of HBV viraemia, faster progression to chronic infection and greater risk of cirrhosis and hepatocellular carcinoma than with HBV infection alone. The immunosuppression that is seen in HIV infection can lead to loss of anti-HBs antibodies, reactivation of infection and a poorer antibody response to HBV vaccination.

Pregnancy poses particular problems in co-infected patients, with increased risk of perinatal transmission of HBV to the child. Treatment can also be problematic. Several nucleoside analogues have dual antiviral activity and some regimens have been associated with emergence of drug resistance. Co-infection is also associated with diminished response to interferons and increased resistance to lamivudine in some patients. Co-infection should be managed by specialists with expertise in this area and combinations of antiviral agents need to be thought through carefully. Antiviral therapy should be considered for co-infected pregnant women, using drugs with dual activity, e.g. tenofovir with emtricitabine or lamivudine.

Globally, there is a need to identify co-infected patients earlier, especially in endemic areas, as well as a need for early effective interventions, particularly in pregnant women, to reduce perinatal transmission.

**Hepatitis D (Delta virus)**

The hepatitis D virus (HDV) is an RNA-defective virus that has no independent existence; it requires HBV for replication and has the same sources and modes of spread. It can infect individuals simultaneously with HBV or can superinfect those who are already chronic carriers of HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals who are chronic carriers of HBV can cause acute hepatitis with spontaneous recovery, and occasionally there is simultaneous cessation of the chronic HBV infection. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a worldwide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers who also carry HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

**Investigations**

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV, followed by full recovery, is associated with the appearance of low titres of anti-HDV of IgM type within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Super-infection of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

**Management**

Effective management of hepatitis B prevents hepatitis D.

**Hepatitis C**

This is caused by an RNA flavivirus. Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are identified only when they develop chronic liver disease. Eighty per cent of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare. There is no active or passive protection against hepatitis C virus (HCV).

Hepatitis C infection is usually identified in asymptomatic individuals screened because they have risk factors for infection, such as previous injecting drug use (Box 22.40), or have incidentally been found to have abnormal liver blood tests. Although most people remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and is unrelated to the degree of liver damage. Hepatitis C is the most common cause of what used to be known as ‘non-A, non-B hepatitis’.

If hepatitis C infection is left untreated, progression from chronic hepatitis to cirrhosis occurs over 20–40 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV), prothrombotic states and heavy alcohol misuse. Not everyone with hepatitis C infection will necessarily develop cirrhosis but approximately 20% do so within 20 years. Once cirrhosis has developed, the 5- and 10-year survival rates are 95% and 81%, respectively. One-quarter of people with cirrhosis will develop complications within 10 years and, once complications such as ascites develop, the 5-year survival is around 50%. Once cirrhosis is present, 2–5% per year will develop primary hepatocellular carcinoma.

**Investigations**

**Serology and virology**

The HCV genome encodes a large polypeptide precursor that is modified post-translationally to at least ten proteins, including several antigens that give rise to antibodies in an infected person; these are used in diagnosis. It may take 6–12 weeks for antibodies to appear in the blood following acute infection, such as a needlestick injury. In these cases, hepatitis C RNA can be identified in the blood as early as 2–4 weeks after infection. Active infection is confirmed by the presence of serum hepatitis C RNA in anyone who is antibody-positive. Anti-HCV antibodies persist in serum even after viral clearance, whether spontaneous or post-treatment.

**Molecular analysis**

There are six common viral genotypes, the distribution of which varies worldwide. Genotype has no effect on progression of liver disease but does affect response to treatment. Genotype 1 is most common in northern Europe and was less easy to eradicate than genotypes 2 and 3 with traditional pegylated interferon alfa–ribavirin-based treatments. Knowledge of viral genotype still remains relevant in guiding selection of drugs to treat HCV.

**Liver function tests**

LFTs may be normal or show fluctuating serum transaminases between 50 and 200 U/L. Jaundice is rare and only usually appears in end-stage cirrhosis.

**22.40 Risk factors for the acquisition of chronic hepatitis C infection**

- Intravenous drug misuse (95% of new cases in the UK)
- Unscreened blood products
- Vertical transmission (3% risk)
- Needlestick injury (3% risk)
- Iatrogenic parenteral transmission (e.g. contaminated vaccination needles)
- Sharing toothbrushes/razors
Liver histology
Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis and so a liver biopsy may be required to stage the extent of liver damage. The degree of inflammation and fibrosis can be scored histologically. The most common way of doing this in hepatitis C is the Metavir system, which scores fibrosis from 1 to 4, the latter equating to cirrhosis. Recently, non-invasive markers and fibrosis scoring systems have been used routinely, with biopsy being reserved for cases where these give conflicting results.

Management
The aim of treatment is to eradicate infection. In recent years, there have been substantial advances, so much so that rates of viral clearance achieved 6 months after finishing treatment (termed sustained virological response, SVR) have risen from less than 40% a decade ago to levels approaching 100% with some of the newer direct-acting antivirals. The infection is cured in more than 99% of patients who achieve an SVR. These newer drugs are extremely expensive, however, and so their use is placing substantial strain on the finite health-care resources of developed countries and has severely limited their availability in resource-poor settings.

Until 2011, the treatment of choice was dual therapy with pegylated interferon-alfa, given as a weekly subcutaneous injection, together with oral ribavirin, a synthetic nucleotide analogue. Treatment was long – up to 12 months for genotype 1 infection, and both agents had significant side-effects that limited tolerability: ribavirin induces haemolytic anaemia and is teratogenic, while interferon induces influenza-like symptoms, irritability and depression, all of which can affect quality of life. As already mentioned, efficacy of these agents was poor (12 months’ treatment for genotype 1 resulted in only a 40% SVR, rising to an SVR of over 70% for genotypes 2 or 3 after 6 months’ treatment).

Since 2011, new classes of direct-acting antiviral agents (DAAs) have been developed. There are four main classes of DAA, which are defined according to their mechanism of action and therapeutic target (Box 22.41). These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt viral replication (Fig. 22.28). Initially, DAAs were added to interferon-/ribavirin-based regimens; more recently, however, combinations of DAAs have increasingly been used in ‘interferon-free’ regimens. This maximises treatment efficacy by directly interfering with replication at multiple points in the viral life cycle without exposing patients to the side-effect profile of interferon-alfa therapy. For example, 12 weeks of treatment with oral sofosbuvir plus ledipasvir plus ribavirin can achieve a 99% SVR in treatment-naïve genotype 1 patients. Sofosbuvir plus velpatasvir achieves similar results and is pan-genotypic. Although not without side-effects, DAAs are often orally administered, efficacious and, in general, well tolerated.

Liver transplantation should be considered when complications of cirrhosis occur, such as diuretic-resistant ascites. Unfortunately, if the virus is not cleared, hepatitis C will infect the transplanted liver and up to 15% of patients then develop cirrhosis in the liver graft within 5 years of transplantation. This should no longer happen, as modern antiviral therapy post-transplant achieves excellent results.

Hepatitis E
Hepatitis E is caused by an RNA virus that is endemic in India and the Middle East. Prevalence is now increasing across Asia and Europe, especially south-west France, so it is important to note that infection is no longer seen only in travellers from an endemic area.

The clinical presentation and management of hepatitis E are similar to those of hepatitis A. Disease is spread via the faecal–oral route or through contaminated food; the virus is commonly present in uncooked game and pig-liver sausage in southern France, and this may be a route of infection. In most cases, it presents as a self-limiting acute hepatitis and does not usually cause chronic liver disease. There is increasing recognition that hepatitis E may develop into chronic infection, usually in immunocompromised patients and especially in organ-transplant recipients, although this remains uncommon. If treatment is required for chronic infection, agents such as ribavirin may be used. Blood donations are now routinely screened for hepatitis E.

Hepatitis E differs from hepatitis A in that infection during pregnancy is associated with the development of acute liver failure, which has a high mortality. In acute infection, IgM antibodies to hepatitis E virus (HEV) are positive.

Other forms of viral hepatitis
Non-A, non-B, non-C (NANBNC) or non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Other viruses that affect the liver probably exist but the viruses described above now account for the majority of hepatitis infections. Cytomegalovirus and EBV infection causes abnormal LFTs in most patients and occasionally jaundice occurs. Herpes simplex is a rare cause of hepatitis in adults, most of whom are immunocompromised. Herpes simplex virus hepatitis can be very severe in pregnancy. Abnormal LFTs are also common in chickenpox, measles, rubella and acute HIV infection.
Liver abscess

Liver abscesses are classified as pyogenic, hydatid or amoebic.

Pyogenic liver abscess

Pyogenic liver abscesses are uncommon but important because they are potentially curable, carry significant morbidity and mortality if untreated, and are easily overlooked. The mortality of liver abscesses is 20–40%; failure to make the diagnosis is the most common cause of death. Older patients and those with multiple abscesses have a higher mortality.

Pathophysiology

Infection can reach the liver in several ways (Box 22.43). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. They can also complicate dental sepsis or colonic pathology, e.g. cancer, diverticulitis or inflammatory bowel disease causing portal pyaemia.

HIV infection and the liver

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 22.42. This topic is discussed in more detail on page 317. Co-infection with HIV and HBV is discussed on page 876.
Abscesses complicating suppurrative appendicitis used to be common in young adults but are now rare. Immunoassessed patients are particularly likely to develop liver abscesses. Single lesions are more common in the right liver; multiple abscesses are usually due to infection secondary to biliary obstruction. Escherichia coli and various streptococci, particularly Strep. milleri, are the most common organisms; anaerobes, including streptococci and Bacteroides, can often be found when infection has been transmitted from large bowel pathology via the portal vein, and multiple organisms are present in one-third of patients.

Clinical features
Patients are generally ill with fever and sometimes rigors and weight loss. Abdominal pain is the most common symptom and is usually in the right upper quadrant, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Tender hepatomegaly is found in more than 50% of patients. Mild jaundice may be present, becoming severe if large abscesses cause biliary obstruction. Atypical presentations are common and explain the frequency with which the diagnosis is made only at autopsy. This is a particular problem in patients with gradually developing illnesses or pyrexia of unknown origin without localising features. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

Investigations
Liver imaging is the most revealing investigation and shows 90% or more of symptomatic abscesses. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. A leucocytosis is frequently found, plasma ALP activity is usually increased, and the serum albumin is often low. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Blood cultures are positive in 50–80%. Abscesses caused by gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

Management
Pending the results of culture of blood and pus from the abscess, treatment should be commenced with a combination of antibiotics, such as ampicillin, gentamycin and metronidazole. Aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or if it does not respond to antibiotics. Any associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Surgical abscess drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or ‘pseudotumour’.

Hydatid cysts and amoebic liver abscesses
These are described on pages 299 and 287.

Leptospirosis
This is described on page 257.

Alcoholic liver disease
Alcohol is one of the most common causes of chronic liver disease worldwide, with consumption continuing to increase in many countries. Patients with alcoholic liver disease (ALD) may also have risk factors for other liver diseases (e.g. coexisting NAFLD or chronic viral hepatitis infection), and these may interact to increase disease severity.

In the UK, a unit of alcohol contains 8 g of ethanol (Box 22.44). An upper threshold of 14 units/week in women and 21 units/week in men is generally considered safe. Recently, however, Public Health England advice has adopted a more conservative threshold of 14 units/week for both men and women. The risk threshold for developing ALD is variable but begins at 30 g/day of ethanol. There is no clear linear relationship between dose and liver damage, however. For many, consumption of more than 80 g/day, for more than 5 years, is required to confer significant risk of advanced liver disease. The average alcohol consumption of a man with cirrhosis is 160 g/day for over 8 years. Some of the risk factors for ALD are:

- Drinking pattern. ALD and alcohol dependence are not synonymous; many of those who develop ALD are not alcohol-dependent and most dependent drinkers have normal liver function. Liver damage is more likely to occur in continuous rather than intermittent or ‘binge’ drinkers, as this pattern gives the liver a chance to recover. It is therefore recommended that people should have at least two alcohol-free days each week. The type of beverage does not affect risk.

- Gender. The incidence of ALD is increasing in women, who have higher blood ethanol levels than men after consuming the same amount of alcohol. This may be related to the reduced volume of distribution of alcohol.

- Genetics. Alcoholism is more concordant in monozygotic than dizygotic twins. While polymorphisms in the genes involved in alcohol metabolism, such as aldehyde dehydrogenase, may alter drinking behaviour, they have not been linked to ALD. The patatin-like phospholipase domain-containing 3 (PNPLA3) gene, also known as adiponutrin, has been implicated in the pathogenesis of both ALD and NAFLD (p. 883).

- Nutrition. Obesity increases the incidence of liver-related mortality by over fivefold in heavy drinkers. Ethanol itself produces 7 kcal/g (29.3 kJ/g) and many alcoholic drinks also contain sugar, which further increases the calorific

*1 unit = 8 g.
Pathophysiology

Alcohol reaches peak blood concentrations after about 20 minutes, although this may be influenced by stomach contents. It is metabolised almost exclusively by the liver via one of two pathways (Fig. 22.29).

Approximately 80% of alcohol is metabolised to acetaldehyde by the mitochondrial enzyme, alcohol dehydrogenase. Acetaldehyde is then metabolised to acetyl-CoA and acetate by aldehyde dehydrogenase. This generates NADH from NAD (nicotinamide adenine dinucleotide), which changes the redox potential of the cell. Acetaldehyde forms adducts with cellular proteins in hepatocytes that activate the immune system, contributing to cell injury.

The remaining 20% of alcohol is metabolised by the microsomal ethanol-oxidising system (MEOS) pathway. Cytochrome CYP2E1 is an enzyme that oxidises ethanol to acetate. It is induced by alcohol, and during metabolism of ethanol it releases oxygen free radicals, leading to lipid peroxidation and mitochondrial damage. The CYP2E1 enzyme also metabolises acetalaminophen, and hence chronic alcoholics are more susceptible to hepatotoxicity from low doses of paracetamol.

It is thought that pro-inflammatory cytokines may also be involved in inducing hepatic damage in alcoholic hepatitis, since endotoxin is released into the blood because of increased gut permeability, leading to release of tumour necrosis factor alpha (TNF-α) and interleukin 1 (IL-1), IL-2 and IL-8 from immune cells. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 22.4, p. 849).

Clinical features

ALD has a wide clinical spectrum, ranging from mild abnormalities of LFTs on biochemical testing to advanced cirrhosis. The liver is often enlarged in ALD, even in the presence of cirrhosis. Stigmata of chronic liver disease, such as palmar erythema, are more common in alcoholic cirrhosis than in cirrhosis of other aetiologies. Alcohol misuse may also cause damage of other organs and this should be specifically looked for (see Box 28.22, p. 1194).

Three types of ALD are recognised (Box 22.46) but these overlap considerably, as do the pathological changes seen in the liver.

Alcoholic fatty liver disease

Alcoholic fatty liver disease (AFLD) usually presents with elevated transaminases in the absence of hepatomegaly. It has a good prognosis and steatosis usually disappears after 3 months of abstinence.

Alcoholic hepatitis

This presents with jaundice and hepatomegaly; complications of portal hypertension may also be present. It has a significantly worse prognosis than AFLD. About one-third of patients die in the acute episode, particularly those with hepatic encephalopathy or a prolonged PT. Cirrhosis often coexists; if not present, it is the likely outcome if drinking continues. Patients with acute alcoholic hepatitis often deteriorate during the first 1–3 weeks in hospital. Even if they abstain, it may take up to 6 months for jaundice to resolve. In patients presenting with jaundice who subsequently abstain, the 3- and 5-year survival is 70%. In contrast, those who continue to drink have 3- and 5-year survival rates of 60% and 34%, respectively.
Alcoholic cirrhosis
Alcoholic cirrhosis often presents with a serious complication, such as variceal haemorrhage or ascites, and only half of such patients will survive for 5 years from presentation. However, most who survive the initial illness and who become abstinent will survive beyond 5 years.

Investigations
Investigations aim to establish alcohol misuse, exclude alternative or additional coexistent causes of liver disease, and assess the severity of liver damage. The clinical history from patient, relatives and friends is important to establish alcohol misuse duration and severity. Biological markers, particularly macrocytosis in the absence of anaemia, may suggest and support a history of alcohol misuse. A raised GGT is not specific for alcohol misuse and may also be elevated in the presence of other conditions, including NAFLD. The level may therefore not return to normal with abstinence if chronic liver disease is present, and GGT should not be relied on as an indicator of ongoing alcohol consumption. The presence of jaundice may suggest alcoholic hepatitis. Determining the extent of liver damage often requires a liver biopsy.

In alcoholic hepatitis, PT and bilirubin are used to calculate a ‘discriminant function’ (DF), also known as the Maddrey score, which enables the clinician to assess prognosis (PT = prothrombin time; serum bilirubin in μmol/L is divided by 17 to convert to mg/dL):

\[
DF = [4.6 \times \text{Increase in PT (sec)}] + \text{Bilirubin (mg/dL)}
\]

A value over 32 implies severe liver disease with a poor prognosis and is used to guide treatment decisions (see below). A second scoring system, the Glasgow score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis and has a cut-off of 9 (Box 22.47).

Management
Cessation of alcohol consumption is the single most important treatment and prognostic factor. Life-long abstinence is the best advice. General health and life expectancy are improved with abstinence if chronic liver disease is present, and GGT may progress to cirrhosis and primary liver cancer (Fig. 22.30B). Cessation of alcohol consumption is the single most important treatment and prognostic factor. Life-long abstinence is the best advice. General health and life expectancy are improved with abstinence if chronic liver disease is present, and GGT should not be relied on as an indicator of ongoing alcohol consumption. The presence of jaundice may suggest alcoholic hepatitis. Determining the extent of liver damage often requires a liver biopsy.

In alcoholic hepatitis, PT and bilirubin are used to calculate a ‘discriminant function’ (DF), also known as the Maddrey score, which enables the clinician to assess prognosis (PT = prothrombin time; serum bilirubin in μmol/L is divided by 17 to convert to mg/dL):

\[
DF = [4.6 \times \text{Increase in PT (sec)}] + \text{Bilirubin (mg/dL)}
\]

A value over 32 implies severe liver disease with a poor prognosis and is used to guide treatment decisions (see below). A second scoring system, the Glasgow score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis and has a cut-off of 9 (Box 22.47).

Non-alcoholic fatty liver disease
Increasingly sedentary lifestyles and changing dietary patterns mean that the prevalence of obesity and insulin resistance has increased worldwide, and so fat accumulation in the liver is a common finding during abdominal imaging studies and on liver biopsy. In the absence of high alcohol consumption (typically, a threshold of <20 g/day for women and <30 g/day for men is adopted), this is called non-alcoholic fatty liver disease (NAFLD).

NAFLD includes a spectrum of progressive liver disease ranging from fatty infiltration alone (steatosis) to fatty infiltration with inflammation (non-alcoholic steatohepatitis, NASH) and may progress to cirrhosis and primary liver cancer (Fig. 22.30B). NAFLD is considered by many to be the hepatic manifestation of the ‘metabolic syndrome’ (p. 730), as it is strongly associated with obesity, dyslipidaemia, type 2 diabetes and hypertension. Estimates vary between populations, although one large European study found NAFLD to be present in 94% of obese patients.
Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH).

**A** Features. Rate of progression is determined by environmental (dietary) and genetic factors. The spectrum of NAFLD.

- Fat infiltration > 5% with or without mild inflammation
- Steatosis + necroinflammation (ballooning, Mallory bodies, megamitochondria)
- Increasing fibrosis, eventually leading to cirrhosis

**B** Metabolic syndrome

Fig. 22.30 Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). A Features. Rate of progression is determined by environmental (dietary) and genetic factors. B The spectrum of NAFLD. FA = fatty acid; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha; VLDL = very low-density lipoprotein)

(body mass index (BMI) >30 kg/m²), 67% of overweight patients (BMI >25 kg/m²) and 25% of normal-weight patients. The overall prevalence of NAFLD in patients with type 2 diabetes ranges from 40% to 70%. Histological NASH has been found in 3–16% of apparently healthy potential living liver donors in Europe and 6–15% in the USA.

Overall, NAFLD is estimated to affect 20–30% of the general population in Western countries and 5–18% in Asia, with about 1 in 10 NAFLD cases exhibiting NASH. The frequency of steatosis varies with ethnicity (45% in Hispanics, 33% in whites and 24% in blacks) and gender (42% white males versus 24% white females) but only a minority of patients will progress to cirrhosis and end-stage liver disease. However, because obesity is common and the prevalence of NAFLD is rising, this still represents a large number of patients, placing a substantial burden on health-care resources. Over a median 12-year follow-up period in a cohort of 619 NAFLD patients, an overall 33.2% risk of death or liver transplantation was observed, with liver-related mortality being the third most common cause of death after cardiovascular disease and extra-hepatic malignancy. NAFLD is the leading cause of liver dysfunction in the non-alcoholic, viral hepatitis-negative population in Europe and North America, and is predicted to become the main aetiology in patients undergoing liver transplantation during the next 5 years.

**Pathophysiology**

The initiating events in NAFLD are based on the development of obesity and insulin resistance, leading to increased hepatic free fatty acid flux. This imbalance between the rate of import/synthesis and the rate of export/catabolism of fatty acids in the liver leads to the development of steatosis. This may be an adaptive response through which hepatocytes store potentially toxic lipids as relatively inert triglyceride. A ‘two-hit’ hypothesis has been proposed to describe the pathogenesis of NAFLD, the ‘first hit’ causing steatosis that then progresses to NASH if a ‘second hit’ occurs. In reality, progression probably follows hepatocellular injury caused by a combination of several different ‘hits’, including:

- oxidative stress due to free radicals produced during fatty acid oxidation
- direct lipotoxicity from fatty acids and other metabolites in the liver
- endoplasmic reticulum stress
- gut-derived endotoxin
- cytokine release (TNF-α etc.) and immune-mediated hepatocellular injury.

Cellular damage triggers cell death and inflammation, which leads to stellate cell activation and development of hepatic fibrosis that culminates in cirrhosis (Fig. 22.30A). As with many other liver diseases, subtle inter-patient genetic variations and environmental factors interact to determine disease progression. Several genetic modifiers of disease severity have been identified, with PNPLA3 and its product, adiponutrin, being the best validated.

This should not be confused with acute fatty liver, which can occur in hepatic mitochondrial cytopathies, e.g. acute fatty liver of pregnancy (p. 1283), or in other situations, e.g. Reye’s syndrome (p. 241) or drug toxicity (sodium valproate, tetracyclines), or with bacterial toxins (e.g. Bacillus cereus). In these, defective mitochondrial beta-oxidation of lipids leads to fat droplet accumulation in hepatocytes and microvesicular steatosis.
Clinical features

NAFLD is frequently asymptomatic, although it may be associated with fatigue and mild right upper quadrant discomfort. It is commonly identified as an incidental biochemical abnormality during routine blood tests or as a fatty liver during an ultrasound or CT scan of the abdomen. Alternatively, patients with progressive NASH may present late in the natural history of the disease with complications of cirrhosis and portal hypertension, such as variceal haemorrhage, or with hepatocellular carcinoma.

The average age of NASH patients is 40–50 years (50–60 years for NASH–cirrhosis); however, the emerging epidemic of childhood obesity means that NASH is present in increasing numbers of younger patients. Recognised independent risk factors for disease progression are age over 45 years, presence of diabetes (or severity of insulin resistance), obesity (BMI >30 kg/m²) and hypertension. These factors help with identification of ‘high-risk’ patient groups. NAFLD is also associated with polycystic ovary syndrome, obstructive sleep apnoea and small-bowel bacterial overgrowth.

Investigations

Investigation of patients with suspected NAFLD should be directed first towards exclusion of excess alcohol consumption and other liver diseases (including viral, autoimmune and other metabolic causes) and then at confirming the presence of NASH, discriminating simple steatosis from NASH and determining the extent of any hepatic fibrosis that is present.

Biochemical tests

There is no single diagnostic blood test for NAFLD. Elevations of serum ALT and AST are modest, and usually less than twice the upper limit of normal. ALT levels fall as hepatic fibrosis increases and the characteristic AST:ALT ratio of <1 seen in NASH reverses (AST:ALT >1) as disease progresses towards cirrhosis, meaning that steatohepatitis with advanced disease may be present even in those with normal-range ALT levels. Other laboratory abnormalities that may be present include non-specific elevations of GGT, low-titre antinuclear antibody (ANA) in 20–30% of patients and elevated ferritin levels.

Other laboratory abnormalities that may be present include non-specific elevations of GGT, low-titre antinuclear antibody (ANA) in 20–30% of patients and elevated ferritin levels.

Although routine blood tests are unable to determine the degree of liver fibrosis/cirrhosis accurately, calculated scores, such as the NAFLD Fibrosis Score and FIB-4 Score, which are based on the results of routinely available blood tests and anthropometrics, have a high negative predictive value for advanced fibrosis/ cirrhosis (Box 22.48) and so can be used to rule out advanced fibrosis in many NAFLD patients. This allows care to focus on those most likely to have advanced disease.

Imaging

Ultrasound is most often used and provides a qualitative assessment of hepatic fat content, as the liver appears ‘bright’ due to increased echogenicity; sensitivity is limited when fewer than 33% of hepatocytes are steatotic, however. CT, MRI or MR spectroscopy offer greater sensitivity for detecting lesser degrees of steatosis, but these are resource-intensive and not widely used. No routine imaging modality can distinguish simple steatosis from steatohepatitis or accurately quantify hepatic fibrosis short of cirrhosis.

Liver biopsy

Liver biopsy remains the ‘gold standard’ investigation for diagnosis and assessment of degree of inflammation and extent of liver fibrosis. The histological definition of NASH is based on a combination of three lesions (steatosis, hepatocellular injury and inflammation; see Fig. 22.30A) with a mainly centrilobular, acinar zone 3 distribution. Specific features include hepatocyte ballooning degeneration with or without acidophil bodies or spotty necrosis and a mild, mixed inflammatory infiltrate. These may be accompanied by Mallory–Denk bodies (also known as Mallory’s hyaline). Perisinusoidal fibrosis is a characteristic feature of NASH. Histological scoring systems are widely used to assess disease severity semi-quantitatively.

It is important to note that hepatic fat content tends to diminish as cirrhosis develops and so NASH is likely to be under-diagnosed in the setting of advanced liver disease, where it is thought to be the underlying cause of 30–75% of cases in which no specific aetiology is readily identified (so-called ‘cryptogenic cirrhosis’).

Management

As it is a marker of the metabolic syndrome, identification of NAFLD should prompt screening for and treatment of cardiovascular risk factors in all patients. It is also necessary to assess whether patients have progressive disease and advanced fibrosis so that liver-targeted treatment can be focused particularly on those patients. While liver biopsy is best able to do this, it is invasive and unsuitable for widespread use outside the specialist care setting. An example of an algorithm for the assessment and risk stratification of patients with NAFLD is provided in Figure 22.31.

Non-pharmacological treatment

Current treatment comprises lifestyle interventions to promote weight loss and improve insulin sensitivity through dietary changes.
and physical exercise. Sustained weight reduction of 7–10% is associated with significant improvement in histological and biochemical NASH severity.

**Pharmacological treatment**

No pharmacological agents are currently licensed specifically for NASH therapy. Treatment directed at coexisting metabolic disorders, such as dyslipidaemia and hypertension, should be given. Although use of HMG-CoA reductase inhibitors (statins) does not ameliorate NAFLD, there does not appear to be any increased risk of hepatotoxicity or other side-effects from these agents, and so they may be used to treat dyslipidaemia. Specific insulin-sensitising agents, in particular glitazones, may help selected patients, while recent results with bezafibrate, a lipid-lowering fibrate, have been encouraging. Positive results with high-dose vitamin E (800 U/day) have been tempered by evidence that high doses may be associated with an increased risk of prostate cancer and all-cause mortality, which has limited its use. Several new medicines are currently in late-phase clinical trials and so liver-targeted pharmacological treatments are likely to be available within the next few years.

**Autoimmune liver and biliary disease**

The liver is an important target for autoimmune injury. The clinical picture is dictated by the nature of the autoimmune process and, in particular, the target cell for immune injury. The disease patterns are quite distinctive for primary hepatocellular injury (in the context of autoimmune hepatitis) and biliary epithelial cell injury (primary biliary cholangitis and primary sclerosing cholangitis).
Autoimmune hepatitis is a disease of immune-mediated liver injury characterised by the presence of serum antibodies and peripheral blood T lymphocytes reactive with self-proteins, a strong association with other autoimmune diseases (Box 22.49), and high levels of serum immunoglobulins – in particular, elevation of IgG. Although most commonly seen in women, particularly in the second and third decades of life, it can develop in either sex at any age. The reasons for the breakdown in immune tolerance in autoimmune hepatitis remain unclear, although cross-reactivity with viruses such as HAV and EBV in immunogenetically susceptible individuals (typically those with human leucocyte antigen (HLA)-DR3 and DR4, particularly HLA-DRB3*0101 and HLA-DRB1*0401) has been suggested as a mechanism.

Pathophysiology

Several subtypes of this disorder have been proposed that have differing immunological markers. Although the different patterns can be associated with variation in disease aspects, such as response to immunosuppressive therapy, histological patterns are similar in the different settings and the basic approach to treatment (complete control of liver injury using immunosuppressive drugs and maintained with appropriate therapy) is the same. The formal classification into disease types has fallen out of favour in recent years.

The most frequently seen autoantibody pattern is high titre of antinuclear and anti-smooth muscle antibodies, typically associated with IgG hyperglobulinaemia (type I autoimmune hepatitis in the old classification), frequently seen in young adult females. Disease characterised by the presence of anti-liver–kidney microsomal (LKM) antibodies, recognising cytochrome P450-IID6 expressed on the hepatocyte membrane, is typically seen in paediatric populations and can be more resistant to treatment than ANA-positive disease. Adult onset of anti-LKM can be seen in chronic HCV infection. This was classified as type II disease in the old system. More recently, a pattern of antibody reactivity with anti-soluble liver antigen (anti-SLA) has been described in typically adult patients, often with aggressive disease and usually lacking autoantibodies of other specificities.

Clinical features

The onset is usually insidious, with fatigue, anorexia and eventually jaundice. The non-specific nature of the early features can lead to the diagnosis being missed in the early disease stages. In about one-quarter of patients the onset is acute, resembling viral hepatitis, but resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Other features include fever, arthralgia, vitiligo and epistaxis. Amenorrhoea can occur. Jaundice is mild to moderate or occasionally absent, but signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, can be present. Associated autoimmune disease, such as Hashimoto’s thyroiditis or rheumatoid arthritis, is often present and can modulate the clinical presentation.

Investigations

Serological tests for autoantibodies are often positive (Box 22.50), but low titres of these antibodies occur in some healthy people and in patients with other inflammatory liver diseases. ANA also occur in connective tissue diseases and other autoimmune diseases (with an identical pattern of homogenous nuclear staining) while anti-smooth muscle antibody has been reported in infectious mononucleosis and a variety of malignant diseases. Anti-microsomal antibodies (anti-LKM) occur particularly in children and adolescents. Elevated serum IgG levels are an important diagnostic and treatment response feature if present, but the diagnosis is still possible in the presence of normal IgG levels. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed. It typically shows interface hepatitis, with or without cirrhosis. Scoring systems, such as the International Autoimmune Hepatitis Group (IAIHG) criteria, are useful for epidemiological study and for assessing trial eligibility but are complex for normal clinical practice.

Management

Treatment with glucocorticoids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone (40 mg/day) is given orally; the dose is then gradually reduced as the patient and LFTs improve. Maintenance therapy should only be instituted once LFTs are normal (as well as IgG if elevated). Approaches to maintenance include reduced-dose prednisolone (ideally, below 5–10 mg/day), usually in the context of azathioprine (1.0–1.5 mg/kg/day). Azathioprine can also be used as the sole maintenance immunosuppressive agent in patients with low-activity disease. Newer agents, such as mycophenolate mofetil (MMF), are increasingly being used but formal evidence to inform practice in this area is lacking. Patients should be monitored for acute exacerbations (LFT and IgG screening with patients alerted

*Patients with antimitochondrial antibody frequently have cholestatic liver function tests and may have primary biliary cholangitis (see text).
to the possible symptoms) and such exacerbations should be treated with glucocorticoids. Although treatment can significantly reduce the rate of progression to cirrhosis, end-stage disease can be seen in patients despite treatment.

**Primary biliary cholangitis**

Primary biliary cholangitis (PBC, known as primary biliary cirrhosis until 2015, when the name was changed to reflect more accurately the disease seen in the modern era) is a chronic, progressive cholestatic liver disease that predominantly affects women aged 30 and over. It is strongly associated with the presence of antimitochondrial antibodies (AMA), which are diagnostic, and is characterised by a granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This, in turn, leads to fibrosis and cirrhosis of the liver. The condition can present with an insidious onset of itching and/or tiredness; it may also frequently be found incidentally as the result of routine blood tests.

**Epidemiology**

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America but is rare in Africa and Asia. There is a strong female-to-male predominance of 9:1; it is also more common among cigarette smokers. Clustering of cases has been reported, suggesting an environmental trigger in susceptible individuals.

**Pathophysiology**

Immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a genetic association with HLA-DR8, together with polymorphisms in a number of other genes regulating the nature of the immune response (e.g. IL-12 and its receptor). AMA is directed at pyruvate dehydrogenase complex, a mitochondrial enzyme complex that plays a key role in cellular energy generation. PBC-specific ANAs (such as those directed at the nuclear pore antigen gp210) have a characteristic staining pattern in immunofluorescence assays (selectively binding to the nuclear rim or nuclear dots), which means that they should not be mistaken for the homogenously staining ANA seen in autoimmune hepatitis. Increases in serum immunoglobulin levels are frequent but, unlike in autoimmune hepatitis, it is typically IgM that is elevated.

Pathologically, chronic granulomatous inflammation destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis. A model of the natural history of the disease process is shown in Figure 22.32.

**Clinical features**

Systemic symptoms such as fatigue are common and may precede diagnosis by years. Pruritus, which can be a feature of any cholestatic disease, is a common presenting complaint and may precede jaundice by months or years. Jaundice is rarely a presenting feature. The itching is usually worse on the limbs. Although there may be right upper abdominal discomfort, fever and rigors do not occur. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis (hepatic osteodystrophy).

Initially, patients are well nourished but weight loss can occur as the disease progresses. Scratch marks may be found in patients with severe pruritus. Jaundice is prominent only late in the disease and can become intense. Xanthomatous deposits occur in a minority, especially around the eyes. Mild hepatomegaly is common and splenomegaly becomes increasingly common as portal hypertension develops. Liver failure may supervene.

**Associated diseases**

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly the sicca syndrome (p. 1038), systemic sclerosis, coeliac disease (p. 805) and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

**Diagnosis and investigations**

The LFTs show a pattern of cholestasis (see Box 22.2, p. 853). Hypercholesterolaemia is common and worsens as disease progresses but appears not to be associated with increased cardiac risk. AMA is present in over 95% of patients; when it is absent, the diagnosis should not be made without obtaining histological evidence and considering cholangiography (typically, MRCP) to exclude other biliary disease. ANA and anti-smooth muscle antibodies are present in around 15% of patients with severe pruritus. Jaundice is prominent only late in the disease and can become intense. Xanthomatous deposits occur in a minority, especially around the eyes. Mild hepatomegaly is common and splenomegaly becomes increasingly common as portal hypertension develops. Liver failure may supervene.
Management

The hydrophilic bile acid ursodeoxycholic acid (UDCA), at a dose of 13–15 mg/kg/day, improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool, and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects; it is therefore widely used in the treatment of PBC and should be regarded as the optimal first-line treatment. Its use is recommended in all clinical guidelines. A significant minority of patients either fail to normalise their LFTs with UDCA or show an inadequate response, and such individuals have an increased risk of developing end-stage liver disease compared to those showing a full response. Obitocholic acid (OCA) is a second-generation bile acid therapeutic that acts as an agonist for the nuclear farnesoid X receptor. It reduces hepatocyte synthesis of bile acids and was approved in 2016 for use in patients showing an inadequate response to UDCA. Immunosuppressants, such as glucocorticoids, azathioprine, penicillamine and ciclosporin, have all been trialled in PBC. None shows overall benefit when given to unselected patients. It is unclear whether these drugs offer benefit to the specific subgroup of patients who do not respond to UDCA and require second-line approaches to treatment.

Liver transplantation should be considered once liver failure has developed and may be indicated in patients with intractable pruritus. Serum bilirubin remains the most reliable marker of declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease will recur in over one-third of patients at 10 years.

Pruritus

This is the main symptom requiring treatment. The cause is unknown, but up-regulation of opioid receptors and increased levels of endogenous opioids may play a role. First-line treatment is with the anion-binding resin colestyramine, which probably acts by binding potential pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16 g/day orally is used. The powder is mixed in orange juice and the main dose (8 g) taken before and after breakfast, when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (most obviously UDCA) and adequate spacing should be used between drugs. Colestyramine is sometimes ineffectual, especially in complete biliary obstruction, and can be difficult for some patients to tolerate. Alternative treatments include rifampicin (150 mg/day, titrated up to a maximum of 600 mg/day as required and contingent on there being no deterioration in LFTs), naltrexone (an opioid antagonist; 25 mg/day initially, increasing up to 300 mg/day), plasmapheresis and a liver support device (e.g. a molecular adsorbent recirculating system, MARS).

Fatigue

Fatigue affects about one-third of patients with PBC. The cause is unknown but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression, hypothyroidism and coeliac disease have been excluded, there is currently no specific treatment. The impact on patients’ lives can be substantial.

Malabsorption

Prolonged cholestasis is associated with steatorrhea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

Bone disease

Osteopenia and osteoporosis are common and normal postmenopausal bone loss is accelerated. Baseline bone density should be measured (p. 989) and treatment started with replacement calcium and vitamin D3. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia is rare.

Overlap syndromes

AMA-negative PBC (‘autoimmune cholangitis’)

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable AMA in the serum. Serum transaminases, serum immunoglobulin levels and titres of ANA tend to be higher than in AMA-positive PBC. The clinical course mirrors classical PBC, however, and these patients should be considered as having a variant of PBC.

PBC/autoimmune hepatitis overlap

A few patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulins and interface hepatitis on liver histology. In such individuals, a trial of glucocorticoid therapy may be beneficial.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a cholestatic liver disease caused by diffuse inflammation and fibrosis; it can involve the entire biliary tree and leads to the gradual obliteration of intrahepatic and extrahepatic bile ducts, and ultimately biliary cirrhosis, portal hypertension and hepatic failure. Although considered as an autoimmune disease, evidence for an autoimmune pathophysiology is weaker than is the case for PBC and autoimmune hepatitis. The incidence is about 6.3/100,000 in Caucasians. Cholangiocarcinoma develops in about 10–30% of patients during the course of the disease.

PSC is twice as common in young men. Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography (Fig. 22.33)
- absence of choledocholithiasis (or history of bile duct surgery)
- exclusion of bile duct cancer, by prolonged follow-up.

The term ‘secondary sclerosing cholangitis’ is used to describe the typical changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in Box 22.51.

Pathophysiology

The cause of PSC is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis (Box 22.52). About two-thirds of patients have coexisting ulcerative colitis, and PSC is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop PSC, particularly those with extensive colitis or pancolitis. The prevalence of PSC is lower in patients with Crohn’s colitis (about 1%). Patients with PSC and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and individuals who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

It is currently believed that PSC is an immunologically mediated disease, triggered in genetically susceptible individuals by toxic
Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Common symptoms include fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation. Physical examination is abnormal in about 50% of symptomatic patients; the most common findings are jaundice and hepatomegaly/splenomegaly. The condition may be associated with many other diseases (Box 22.52).

Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy, and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found at a late stage only. In addition to ANCA, low titres of serum ANA and anti-smooth muscle antibodies may be found in PSC but have no diagnostic significance; serum AMA is absent.

The key investigation is now MRCP, which is usually diagnostic and reveals multiple irregular stricturing and dilatation (Fig. 22.33). ERCP should be reserved for when therapeutic intervention is likely to be necessary and should follow MRCP.

On liver biopsy, the characteristic early features of PSC are periductal ‘onion skin’ fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts (Fig. 22.34). Later, fibrosis spreads, progressing inevitably to biliary cirrhosis; obliterative cholangitis leads to the so-called ‘vanishing bile duct syndrome’.

Management

There is no cure for PSC but management of cholestasis and its complications and specific treatment of the disease process are indicated. UDCA is widely used, although the evidence to support this is limited. UDCA may have benefit in terms of reducing colon carcinoma risk.

The course of PSC is variable. In symptomatic patients, median survival from presentation to death or liver transplantation is about 12 years. About 75% of asymptomatic patients survive 15 years or more. Most patients die from liver failure, about 30% die from bile duct carcinoma, and the remainder die from colonic cancer or complications of colitis. Immunosuppressive agents, including...
precislonoi, azathioprine, methotrexate and ciclosporin, have been tried; results have generally been disappointing.

Symptomatic patients often have pruritus. Management is as for PBC. Fatigue appears to be less prominent than in PBC, although it is still present in some patients.

Management of complications

Broad-spectrum antibiotics (e.g., ciprofloxacin) should be given for acute attacks of cholangitis but have no proven value in preventing attacks. If cholangiography shows a well-defined obstruction to the extrahepatic bile ducts (‘dominant stricture’), mechanical relief can be obtained by placement of a stent or by balloon dilatation performed at ERCP. It is important, in this situation, to give active consideration to the possibility of cholangiocarcinoma (the differential diagnosis for a dominant extrahepatic stricture). Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that requires treatment (p. 1044).

Surgical treatment

Surgical resection of the extrahepatic bile duct and biliary reconstruction have a limited role in the management of non-cirrhotic patients with dominant extrahepatic disease. Orthotopic transplantation is the only surgical option in patients with advanced liver disease; 5-year survival is 80–90% in most centres. Unfortunately, the condition may recur in the graft and there are no identified therapies able to prevent this. Cholangiocarcinoma is a contraindication to transplantation. Colon carcinoma risk can be increased in patients following transplantation because of the effects of immune suppression, and enhanced surveillance should be instituted.

IgG4-associated cholangitis

This disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in more than 90% of the patients; p. 841). IgG4-associated cholangitis (IAC) often presents with obstructive jaundice (due to either hilar stricturing/ intrahepatic sclerosing cholangitis or a low bile duct stricture), and cholangiographic appearances suggest PSC with or without hilar cholangiocarcinoma. The serum IgG4 is often raised and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. An important observation is that, compared to PSC, IAC appears to respond well to glucocorticoid therapy.

Liver tumours and other focal liver lesions

Identification of a hepatic mass lesion is common, both in patients with known pre-existing liver disease and as a primary presentation. Although primary and secondary malignant tumours are important potential diagnoses, benign disease is frequent. The finding of a liver mass, with its association in the minds of the patients with metastatic malignant disease, creates a high level of anxiety, a factor that should always be borne in mind. The critical steps to be taken in diagnosing hepatic mass lesions are:

- determining the presence, nature and severity of any underlying chronic liver disease, as the differential diagnosis is very different in patients with and those without chronic liver disease
- using optimal (usually multiple) imaging modalities.

Primary malignant tumours

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the most common primary liver tumour, and the sixth most frequent cause of cancer worldwide. Cirrhosis is present in 75–90% of individuals with HCC and is an important risk factor for the disease. The risk is between 1% and 5% in cirrhosis caused by hepatitis B and C. There is also an increased risk in cirrhosis due to haemochromatosis, alcohol, NASH and α1-antitrypsin deficiency. In northern Europe, 90% of those with HCC have underlying cirrhosis, compared with 30% in Taiwan, where hepatitis B is the main risk factor. The age-adjusted incidence rates vary from 28 per 100,000 in South-east Asia (reflecting the prevalence of hepatitis B) to 10 per 100,000 in southern Europe and 5 per 100,000 in northern Europe. Chronic hepatitis B infection increases the risk of HCC 100-fold and is the major risk factor worldwide. The risk of HCC is 0.4% per year in the absence of cirrhosis and 2–6% in cirrhosis. The risk is four times higher in HBeAg-positive individuals than in those who are HBeAg-negative. Hepatitis B vaccination has led to a fall in HCC in countries with a high prevalence of hepatitis B. The incidence in Europe and North America has risen recently, probably related to the increased prevalence of hepatitis C and NASH cirrhosis. The risk is higher in men and rises with age.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single nodule or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, while lung and bone metastases are rare. Well-differentiated tumours can resemble normal hepatocytes and can be difficult to distinguish from normal liver.

Clinical features

Patients typically present with HCC in one of two ways. Commonly, liver function deteriorates in those with underlying cirrhosis, with worsening ascites and/or jaundice or variceal haemorrhage. Other characteristic symptoms can include weight loss, anorexia and abdominal pain. This often-rapid deterioration can, however, be the event that leads to previously occult cirrhosis becoming clinically apparent, meaning that absence of an established diagnosis of cirrhosis does not preclude a diagnosis of HCC complicating cirrhosis. Examination may reveal hepatomegaly or a right hypochondriacal mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur. The advanced nature of disease that presents in this way makes curative therapy unlikely.

The second presentation is through screening of patients at risk of HCC. The disease is typically detected much earlier in its natural history, significantly increasing the treatment options.

Investigations

Serum markers

Alpha-fetoprotein (AFP) is produced by 60% of HCCs. Levels increase with the size of the tumour and are often normal or only minimally elevated in small tumours detected by ultrasound screening. Serum AFP can also rise in the presence of active hepatitis B and C viral replication; very high levels are seen in acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to
be interpreted with caution. Nevertheless, in the absence of a marked hepatic flare of disease, a progressively rising AFP, or AFP of >400 ng/mL (330 IU/mL; normal is <10 ng/mL (8 IU/mL), warrants an aggressive search for HCC. In HCC patients with elevated AFP levels, serial measurements can be a useful biomarker of disease progression or response to treatment.

Imaging

Ultrasound will detect focal liver lesions as small as 2–3 cm. The use of ultrasound contrast agents has increased sensitivity and specificity but is highly user-dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. Multidetector row CT, following intravenous contrast, identifies HCC by its classical hypervascular appearance (Fig. 22.35). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. MRI can be used instead. Angiography is now seldom performed and has been superseded by the above techniques. A combination of imaging modalities more accurately diagnoses and stages the extent of disease, and use of at least two modalities (typically, CT or MRI following initial screening ultrasound identification of a mass lesion) is recommended.

Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided in patients who may be eligible for transplantation or surgical resection because there is a small (<2%) risk of tumour seeding along the needle tract. In all cases of potential HCC where biopsy is being considered, the impact that a confirmed diagnosis will have on therapy must be weighed against the risks of bleeding. If biopsy will not change management, then its appropriateness should be considered carefully.

Role of screening

Screening for HCC, by ultrasound scanning and AFP measurements at 6-month intervals, is indicated in high-risk patients who would be suitable for therapy if diagnosed with HCC. These include individuals with cirrhosis caused by hepatitis B and C, haemochromatosis, alcohol, NASH and α₁-antitrypsin deficiency. Screening may also be indicated in those with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although no randomised controlled studies of outcome have been undertaken, screening identifies smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation. The role of screening in other forms of chronic liver disease, such as autoimmune hepatitis and PBC, is unclear. This is compounded by the fact that disease staging by biopsy is no longer standard practice in conditions such as PBC, so formal documentation of the presence of cirrhosis, which might be the trigger for commencement of HCC screening, rarely takes place.

Management

This is different for patients with cirrhosis and those without. In the presence of cirrhosis, tumour size, multicity, extent of liver disease (Child–Pugh score) and performance status dictate therapy. An algorithm for managing those with cirrhosis is shown in Figure 22.36.

Prognosis depends on tumour size, the presence of vascular invasion, and liver function in those with cirrhosis. Screening has improved the outlook through early detection.

Hepatic resection

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. There is a 50% recurrence rate at 5 years, however, which may be due to a second de novo tumour or recurrence of the original tumour. Few patients with cirrhosis are suitable for hepatic resection because of the high risk of hepatic failure; nevertheless, surgery is offered, particularly in the Far East, to some cirrhotic patients with small tumours and good liver function (Child–Pugh A with no portal hypertension).

Liver transplantation

Transplantation has the benefit of curing underlying cirrhosis and removing the risk of a second, de novo tumour in an at-risk patient. The requirement for immunosuppression creates its own risks of reactivation, however, if residual or metastatic disease is present, and assessment of patients for suitability for liver transplantation focuses on the exclusion of extrahepatic disease and vascular invasion. The 5-year survival following liver transplantation is 75% for patients with single tumours of less than 5 cm in size or three tumours smaller than 3 cm (the Milan criteria). Unfortunately, the underlying liver disease, in particular hepatitis C, may recur in the transplanted liver and can result in recurrent cirrhosis that gives rise to a de novo HCC risk, now complicated by the presence of immunosuppression.

Percutaneous therapy

Percutaneous ethanol injection into the tumour under ultrasound guidance is efficacious (80% cure rate) for tumours of 3 cm or less. Recurrence rates (50% at 3 years) are similar to those following surgical resection. Radiofrequency ablation, using a single electrode inserted into the tumour under radiological guidance, is an alternative that takes longer to perform but may cause more complete tumour necrosis. Improvements in percutaneous therapy, with the combination of low patient impact, relative efficacy and capacity for repeat treatment, are making these approaches attractive, particularly when major surgery would be inappropriate. Their role in primary therapy as an alternative to curative resection or transplantation is yet to be established.

![Computed tomogram showing a large hepatocellular carcinoma (arrows). Courtesy of Dr D. Redhead, Royal Infirmary of Edinburgh.](image-url)
malignant hepatocytes surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. This variant of HCC has a better prognosis following surgery than an equivalent-sized HCC, two-thirds of patients surviving beyond 5 years.

Other primary malignant tumours

These are rare but include haemangio-endothelial sarcomas. Cholangiocarcinoma (bile duct cancer) typically presents with bile duct obstruction rather than as a hepatic mass lesion, although the latter occasionally occurs.

Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

Clinical features

The primary neoplasm is asymptomatic in 50% of patients, being detected on either radiological, endoscopic or blood biochemistry screening. There is liver enlargement and weight loss; jaundice may be present.

Investigations

A raised ALP activity is the most common biochemical abnormality but LFTs may be normal. Ascitic fluid, if present, has a high protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging shows filling defects (Fig. 22.37); laparoscopy may reveal the tumour and facilitates liver biopsy.

Trans-arterial chemo-embolisation

Hepatocellular cancers are not radiosensitive and the response rate to chemotherapy with drugs, such as doxorubicin, is only around 30%. In contrast, hepatic artery embolisation with absorbable gelatin powder (Gelfoam) and doxorubicin is more effective, with survival rates of 60% in cirrhotic patients with unresectable HCC and good liver function (compared with 20% in untreated patients) at 2 years. Unfortunately, any survival benefit is lost at 4 years. Trans-arterial chemo-embolisation (TACE) is contraindicated in decompensated cirrhosis and multifocal HCC. TACE is now most frequently used as a holding first intervention while the tumour is being assessed and the definitive management plan is being developed.

Chemotherapy

Sorafenib improves survival from 7.9 to 10.7 months in cirrhotic patients. The drug is a multikinase inhibitor with activity against Raf, vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) signalling, and is the first systemic therapy to prolong survival in HCC. The ultimate role of sorafenib in HCC – in particular, when and how best to use it – is yet to be established.

Fibrolamellar hepatocellular carcinoma

This rare variant differs from HCC in that it occurs in young adults, equally in males and females, in the absence of hepatitis B infection and cirrhosis. The tumours are often large at presentation and the AFP is usually normal. Histology of the tumour reveals
Drugs and the liver

Consist of nodular regeneration of hepatocytes without fibrosis. They may be multiple but only rarely need resection.

Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 22.39). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, palliative treatment to relieve pain is all that is available for most patients; this may include arterial embolisation of the tumour masses.

Management

Hepatic resection can improve survival for slow-growing tumours, such as colonic carcinomas, and is an approach that should be actively explored in patients who are fit for liver resection and have had the primary tumour resected once extrahepatic disease has been excluded. Patients with neuro-endocrine tumours, such as gastrinomas, insulinomas and glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients; this may include arterial embolisation of the tumour masses.

Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

Hepatic adenomas

These are rare vascular tumours that may present as an abdominal mass, or with abdominal pain or intraperitoneal bleeding. They are more common in women and may be caused by oral contraceptives, androgens and anabolic glucocorticoids. Resection is indicated for the relief of symptoms. Hepatic adenomas can increase in size during pregnancy. Large or rapidly growing adenomas can rarely rupture, causing intraperitoneal bleeding.

Haemangiomas

These are the most common benign liver tumours and are present in 1–20% of the population. Most are smaller than 5 cm and rarely cause symptoms (Fig. 22.38). The diagnosis is usually made by ultrasound but CT may show a low-density lesion with delayed arterial filling. Surgery is needed only for very large symptomatic lesions or where the diagnosis is in doubt.

Focal nodular hyperplasia

Focal nodular hyperplasia is common in women under the age of 40. The lesions are usually asymptomatic but can be up to 10 cm in diameter; they can be differentiated from adenoma by a focal central scar seen on CT or MRI. Histologically, they consist of nodular regeneration of hepatocytes without fibrosis. They may be multiple but only rarely need resection.

Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 22.39). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, palliative treatment to relieve pain is all that is available for most patients; this may include arterial embolisation of the tumour masses.

Drugs and the liver

The liver is the primary site of drug metabolism and an important target for drug-induced injury. Pre-existing liver disease may affect the capacity of the liver to metabolise drugs and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses (p. 32). Box 22.53 also shows drugs that should be avoided in patients with cirrhosis, as they can exacerbate known complications of cirrhosis. The possibility of undiagnosed underlying liver injury should always be considered in patients exhibiting unexpected effects following drug exposure.
Drug-induced liver injury

Drug toxicity should always be considered in the differential diagnosis of patients presenting with acute liver failure, jaundice or abnormal liver biochemistry. Some typical patterns of drug toxicity are listed in Box 22.54; the most common picture is a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to normalise following a drug-induced hepatitis, and it may be months before they normalise after a cholestatic hepatitis. Occasionally, permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

The key to diagnosing acute drug-induced liver disease is to take a detailed drug history (Box 22.55), looking for temporal relationships between drug exposure and onset of liver abnormality (bearing in mind the fact that liver injury can frequently take weeks or even months to develop following exposure). A liver biopsy should be considered if there is suspicion of pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Where drug-induced liver injury is suspected or cannot be excluded, the potential culprit drug should be discontinued unless it is impossible to do so safely.

Types of liver injury

Different histological patterns of liver injury may occur with drug injury.

Cholestasis

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was common when high concentrations of oestrogens (50 μg/day) were used as contraceptives. Both the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canalicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic glucocorticoids used by body-builders may also cause a cholestatic hepatitis. In some cases (e.g. NSAIDs and cyclo-oxygenase 2 (COX-2) inhibitors), there is overlap with acute hepatocellular injury.

Hepatocyte necrosis

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granulomas may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies, including germander, comfrey and jin bu huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

Steatosis

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate. Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone toxicity can produce a similar histological picture to NASH.

Vascular/sinusoidal lesions

Drugs such as the alkylating agents used in oncology can damage the vascular endothelium and lead to hepatic venous
outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

Hepatic fibrosis
Most drugs cause reversible liver injury and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

Inherited liver diseases
The inherited diseases are an important and probably under-diagnosed group of liver diseases. In addition to the ‘classical’ conditions, such as haemochromatosis and Wilson’s disease, the important role played by the liver in the expression of the inborn errors of metabolism should be remembered, as should the potential for genetic underpinning for intrahepatic cholestasis.

Haemochromatosis
Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 22.56).

Hereditary haemochromatosis
In hereditary haemochromatosis (HHC), iron is deposited throughout the body and total body iron may reach 20–60 g (normally 4 g). The important organs involved are the liver, pancreatic islets, endocrine glands, joints and heart. In the liver, iron deposition occurs first in the periportal hepatocytes, extending later to all hepatocytes. The gradual development of fibrous septa leads to the formation of irregular nodules, and finally regeneration results in macronodular cirrhosis. An excess of liver iron can occur in alcoholic cirrhosis but this is mild in comparison with haemochromatosis.

Pathophysiology
The disease is caused by increased absorption of dietary iron and is inherited as an autosomal recessive trait. Approximately 90% of patients are homozygous for a single point mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein, which has structural and functional similarity to the HLA proteins. The mechanisms by which HFE regulates iron absorption are unclear. It is believed, however, that HFE normally interacts with the transferrin receptor in the basolateral membrane of intestinal epithelial cells. In HHC, it is thought that the lack of functional HFE causes a defect in uptake of transferrin-associated iron, leading to up-regulation of enterocyte iron-specific divalent metal transporters and excessive iron absorption. A histidine-to-aspartic acid mutation at position 63 (H63D) in HFE causes a less severe form of haemochromatosis that is most commonly found in patients who are compound heterozygotes also carrying a C282Y mutated allele. Fewer than 50% of C282Y homozygotes will develop clinical features of haemochromatosis; therefore other factors must also be important. HHC may promote accelerated liver disease in patients with alcohol excess or hepatitis C infection. Iron loss in menstruation and pregnancy can delay the onset of HHC in females.

Clinical features
Symptomatic disease usually presents in men over 40 years of age with features of liver disease (often with hepatomegaly), type 2 diabetes or heart failure. Fatigue and arthropathy are early symptoms but are frequently absent. Leaden-grey skin pigmentation due to excess melanin occurs, especially in exposed parts, axillae, groins and genitalia: hence the term ‘bronzed diabetes’. Once again, absence of this feature does not preclude the diagnosis. Impotence, loss of libido and testicular atrophy are recognised complications, as are early-onset osteoarthritis targeting unusual sites such as the metacarpophalangeal joints, chondrocalcinosis and pseudogout. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.

Investigations
Serum iron studies show a greatly increased ferritin, a raised plasma iron and saturated plasma iron-binding capacity. Transferrin saturation of more than 45% is suggestive of iron overload. Significant liver disease is unusual in patients with ferritin lower than 1000 μg/L (100 μg/dL). The differential diagnoses for elevated ferritin are inflammatory disease or excess ethanol consumption for modest elevations (<1000 μg/L (100 μg/dL)). Very significant ferritin elevation can be seen in adult Still’s disease. In terms of imaging techniques, MRI has high specificity for iron overload but poor sensitivity. Liver biopsy allows assessment of fibrosis and distribution of iron (hepatocyte iron characterisation of haemochromatosis). The Hepatic Iron Index (HII) provides quantification of liver iron (μmol of iron per g dry weight of liver/age in years). An HII of more than 1.9 suggests genetic haemochromatosis (Fig. 22.40). Both the C282Y and the H63D mutations can be identified by genetic testing, which is now in routine clinical use.

Management
Treatment consists of weekly venesection of 500 mL blood (250 mg iron) until the serum iron is normal; this may take 2 years or more. The aim is to reduce ferritin to under 50 μg/L (5 μg/dL). Thereafter, venesection is continued as required to keep the serum ferritin normal. Liver and cardiac problems
improve after iron removal, but joint pain is less predictable and can improve or worsen after iron removal. Type 2 diabetes does not resolve after venesection. Other therapy includes that for cirrhosis and diabetes. First-degree family members should be investigated, preferably by genetic screening and also by checking the plasma ferritin and iron-binding saturation. Liver biopsy is indicated in asymptomatic relatives only if the LFTs are abnormal and/or the serum ferritin is greater than 1000 μg/L (100 μg/dL) because these features are associated with significant fibrosis or cirrhosis. Asymptomatic disease should also be treated by venesection until the serum ferritin is normal.

Pre-cirrhotic patients with HHC have a normal life expectancy, and even cirrhotic patients have a good prognosis compared with other forms of cirrhosis (three-quarters of patients are alive 5 years after diagnosis). This is probably because liver function is well preserved at diagnosis and improves with therapy. Screening for hepatocellular carcinoma (p. 890) is mandatory because this is the main cause of death, affecting one-third of patients with cirrhosis, irrespective of therapy. Venesection reduces but does not abolish the risk of hepatocellular carcinoma in the presence of cirrhosis.

## Secondary haemochromatosis

Many conditions, including chronic haemolytic disorders, sideroblastic anaemia, other conditions requiring multiple blood transfusion (generally over 50 L), porphyria cutanea tarda, dietary iron overload and occasionally alcoholic cirrhosis, are associated with widespread secondary siderosis. The features are similar to those of primary haemochromatosis but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for the HFE gene and this may contribute to the development of iron overload.

## Wilson’s disease

Wilson’s disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism caused by a variety of mutations in the ATP7B gene on chromosome 13. Total body copper is increased, with excess copper deposited in, and causing damage to, several organs.

### Pathophysiology

Normally, dietary copper is absorbed from the stomach and proximal small intestine and is rapidly taken into the liver, where it is stored and incorporated into ceruloplasmin, which is secreted into the blood. The accumulation of excessive copper in the body is ultimately prevented by its excretion, the most important route being via bile. In Wilson’s disease, there is almost always a failure of synthesis of ceruloplasmin; however, some 5% of patients have a normal circulating ceruloplasmin concentration and this is not the primary pathogenic defect. The amount of copper in the body at birth is normal but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

The ATP7B gene encodes a member of the copper-transporting P-type adenosine triphosphatase family, which functions to export copper from various cell types. At least 200 different mutations have been described. Most cases are compound heterozygotes with two different mutations in ATP7B. Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns. The large number of culprit mutations means that, in contrast to haemochromatosis, genetic diagnosis is not routine in Wilson’s disease, although it may have a role in screening families following identification of the genotype in an index patient.

### Clinical features

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence, although it can present in adults in their fifties. Neurological damage causes basal ganglion syndromes and dementia, which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

### Liver disease

Episodes of acute hepatitis, sometimes recurrent, can occur, especially in children, and may progress to fulminant liver failure. The latter is characterised by the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. Chronic hepatitis can also develop insidiously and eventually present with established cirrhosis; liver failure and portal hypertension may supervene. The possibility of Wilson’s disease should be considered in any patient under the age of 40 presenting with recurrent acute hepatitis or chronic liver disease of unknown cause, especially when this is accompanied by haemolysis.

### Neurological disease

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia (Ch. 25). Unusual clumsiness for age may be an early symptom. Neurological disease typically develops after the onset of liver disease and can be prevented by effective treatment started following diagnosis in the liver disease phase. This increases the importance of diagnosis in the liver phase beyond just allowing effective management of liver disease.

### Kayser–Fleischer rings

These constitute the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson’s disease (less often in children but almost always in neurological...
Wilson’s disease, albeit sometimes only by slit-lamp examination. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery (p. 846). They disappear with treatment.

**Investigations**

A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. Advanced liver failure from any cause can, however, reduce the serum caeruloplasmin and occasionally it is normal in Wilson’s disease. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than 0.6 μmol/24 hrs (38 μg/24 hrs) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion while giving D-penicillamine is a useful confirmatory test: more than 25 μmol/24 hrs is considered diagnostic of Wilson’s disease.

**Management**

The copper-binding agent penicillamine is the drug of choice. The dose given must be sufficient to produce cupriuresis and most patients require 1.5 μg/day (range 1–4 μg). The dose can be reduced once the disease is in remission but treatment must continue for life, even through pregnancy. Care must be taken to ensure that re-accumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these do arise, trientine dihydrochloride (1.2–2.4 μg/day) and zinc (50 mg 3 times daily) are potential alternatives.

Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson’s disease is unclear. Prognosis is excellent, provided treatment is started before there is irreversible damage. Siblings and children of patients with Wilson’s disease must be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

**Alpha1-antitrypsin deficiency**

Alpha1-antitrypsin (α1-AT) is a serine protease inhibitor (Pi) produced by the liver. One of its main anti-protease functions is the breakdown of neutrophil elastase. The mutated form of α1-AT (PiZ) cannot be secreted into the blood by liver cells because it is retained within the endoplasmic reticulum of the hepatocyte. Homozygous individuals (PiZZ) have low plasma α1-AT concentrations, although globules containing α1-AT are found in the liver, and these people may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously; chronic hepatitis and cirrhosis in adults; and, in the long term, HCC. Alpha1-AT deficiency is a not uncommon exacerbating factor for liver disease of other aetiologies, and the possibility of dual pathology should be considered when severity of disease, such as ALD, appears disproportionate to the level of underlying insult.

There are no clinical features that distinguish liver disease due to α1-AT deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma α1-AT concentration and genotyping for the presence of the mutation. Alpha1-AT-containing globules can be demonstrated in the liver (Fig. 22.41) but this is not necessary to make the diagnosis. Occasionally, patients with liver disease and minor reductions of plasma α1-AT concentrations have α1-AT variants other than PiZZ, but the relationship of these to liver disease is uncertain. There is no specific treatment. The risk of severe and early-onset emphysema means that all patients should be advised to stop smoking.

**Gilbert’s syndrome**

Gilbert’s syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 22.17, p. 860). It is an autosomal recessive trait when caused by a mutation in the promoter region of the gene for UDP-glucuronoyl transferase enzyme (UGT1A1), which leads to reduced enzyme expression. It can be inherited in a dominant fashion when there is a missense mutation in the gene. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronoyl transferase.

**Clinical features**

The typical presentation is with isolated elevation of bilirubin, typically, although not exclusively, in the setting of physical stress or illness. There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence stercobilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed. In the presence of haemolysis, pallor due to anaemia and splenomegaly due to excessive reticulo-endothelial activity are usually present.

**Investigations**

The plasma bilirubin is usually less than 100 μmol/L (~6 mg/dL) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Hepatic histology is normal and liver biopsy is not recommended for the investigation of patients with possible Gilbert’s syndrome. The condition is not associated with liver injury and thus has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.
Vascular liver disease

Metabolically, the liver is highly active and has large oxygen requirements. This places it at risk of ischaemic injury in settings of impaired perfusion. The risk is mitigated, however, by the dual perfusion of the liver (via the portal vein as well as hepatic artery), with the former representing a low-pressure perfusion system that offers protection against the potential effects of arterial hypotension. The single outflow through the hepatic vein and the low-pressure perfusion system of the portal vein make the liver vulnerable to venous thrombotic ischaemia in the context of Budd–Chiari syndrome and portal vein thrombosis, respectively.

Hepatic arterial disease

Liver ischaemia

Liver ischaemic injury is relatively common during hypotensive or hypoxic events and is under-diagnosed. The characteristic pattern is one of rising transaminase values in the days following such an event (e.g. prolonged seizures). Liver synthetic dysfunction and encephalopathy are uncommon but can occur. Liver failure is very rare. Diagnosis typically rests on clinical suspicion and exclusion of other potential aetiologies. Treatment is aimed at optimising liver perfusion and oxygen delivery. Outcome is dictated by the morbidity and mortality associated with the underlying disease, given that liver ischaemia frequently occurs in the context of other organ ischaemia in high-risk patients.

Liver arterial disease

Hepatic arterial disease is rare outside the setting of liver transplantation and is difficult to diagnose. It can cause significant liver damage. Hepatic artery occlusion may result from inadvertent injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually >1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic arterial aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis and surgical or biopsy trauma are the main causes. They usually lead to bleeding into the biliary tree, peritoneum or intestine and are best diagnosed by angiography. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery but this rarely causes symptoms.

Hepatic artery thrombosis is a recognised complication of liver transplantation and typically occurs in the early post-transplant period. Clinical features are often related to bile duct rather than liver ischaemia because of the dominant role of the hepatic artery in extrahepatic bile duct perfusion. Manifestations can include bile duct anastomotic failure with bile leak or the development of late bile duct strictures. Diagnosis and initial intervention are radiological in the first instance, with ERCP and biliary stenting being the principal approaches to the treatment of bile duct injury.

Portal vein thrombosis

Portal venous thrombosis as a primary event is rare but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may rarely lead to bowel infarction, requiring surgery. Treatment is otherwise based on anticoagulation, although there are no randomised data that demonstrate efficacy. An underlying thrombophilia needs to be excluded. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension (p. 868). Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low. Portal vein thrombosis can arise as a secondary event in patients with cirrhosis and portal hypertension, and is a recognised cause of decompensation in patients with previously stable cirrhosis. In individuals showing such decompensation, portal vein patency should be assessed by ultrasound with Doppler flow studies.

Hepatopulmonary syndrome

This condition is characterised by resistant hypoxaemia ($\text{PaO}_2 <9.3$ kPa (70 mmHg)), intrapulmonary vascular dilatation in patients with cirrhosis, and portal hypertension. Clinical features include finger clubbing, cyanosis, spider naevi and a characteristic reduction in arterial oxygen saturation on standing. The hypoxia is due to intrapulmonary shunting through direct arteriovenous communications. Nitric oxide (NO) over-production may be important in pathogenesis. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe ($\text{PaO}_2 <6.7$ kPa (50 mmHg)), is associated with an increased operative risk.

Portopulmonary hypertension

This unusual complication of portal hypertension is similar to ‘primary pulmonary hypertension’ (p. 621). It is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. The condition is caused by vasoconstriction and obliteration of the pulmonary arterial system and leads to breathlessness and fatigue.

Hepatic venous disease

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart (see Fig. 22.20, p. 868). The clinical features depend on the cause and on the speed with which obstruction develops, and can mimic many other forms of chronic liver disease, sometimes leading to delayed diagnosis. Congestive hepatomegaly and ascites are, however, the most consistent features. The possibility of hepatic venous obstruction should always be considered in patients with an atypical liver presentation.

Budd–Chiari syndrome

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Many patients have haematological disorders such as myelofibrosis, primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria,
or antithrombin III, protein C or protein S deficiencies (Ch. 23). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena caval stenosis are the other main causes. The underlying cause cannot be found in about 50% of patients, although this percentage is falling as molecular diagnostic tools (such as the JAK2 mutation in myelofibrosis) increase our capacity to diagnose underlying haematological disorders. Hepatic congestion affecting the centrilobular areas is followed by centrilobular fibrosis, and eventually cirrhosis supervenes in those who survive long enough.

Clinical features
Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and, often, upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.

Investigations
The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis. Ascitic fluid analysis shows a protein concentration above 25 g/L (2.5 g/dL) (exudate) in the early stages; this often falls later in the disease, however. Doppler ultrasound may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as this often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is needed only if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

Management
Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, thrombolysis with streptokinase, followed by heparin and oral anticoagulation, should be considered. Ascites is initially treated medically but often with limited success. Short hepatic venous strictures can be treated with angioplasty. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPS, followed by anticoagulation. Surgical shunts, such as portacaval shunts, are less commonly performed now that TIPS is available. Occasionally, a web can be resected or an inferior vena cava stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

Prognosis without transplantation or shunting is poor, particularly following an acute presentation with liver failure. A 3-year survival of 50% is reported in those who survive the initial event. The 1- and 10-year survival following liver transplantation is 85% and 69%, respectively, and this compares with a 5- and 10-year survival of 87% and 37%, respectively, following surgical shunting.

Sinusoidal obstruction syndrome
(Seno-occlusive disease)
Sinusoidal obstruction syndrome (SOS; previously known as veno-occlusive disease) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in Senecio and Heliotropium plants used to make teas, as well as cytotoxic drugs and hepatic irradiation, are all recognised causes. SOS may develop in 10–20% of patients following haematopoietic stem cell transplantation (usually within the first 20 days) and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting, SOS is thought to relate to pre-conditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous outflow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may facilitate the diagnosis. Traditionally, treatment has been supportive but defibrotide shows promise (the drug binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation).

Cardiac disease
Hepatic damage, due primarily to congestion, may develop in all forms of right heart failure (p. 461); usually, the clinical features are predominantly cardiac. Very rarely, long-standing cardiac failure and hepatic congestion give rise to cardiac cirrhosis. Severe left ventricular dysfunction is a cause of ischaemic hepatitis. Cardiac causes of acute and chronic liver disease are typically under-diagnosed. Treatment is principally that of the underlying heart disease with supportive treatment for the liver component.

Nodular regenerative hyperplasia of the liver
This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. It is believed to be due to damage to small hepatic arterioles and portal venules. It occurs in older people and is associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs, such as azathioprine. The condition is usually asymptomatic but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis is very favourable. Management is based on treatment of the portal hypertension.

Pregnancy and the liver
The inter-relationship between liver disease and pregnancy can be a complex one and a source of real anxiety for both patient and clinician. Three possibilities need to be borne in mind when treating a pregnant woman with a liver abnormality:

• This represents a worsening of pre-existing chronic liver or biliary disease (although pregnancy may be the first time a woman’s liver biochemistry has been tested, so this may not have previously been diagnosed).
• This represents a genuine first presentation of liver disease that is not intrinsically related to pregnancy.
• This represents a genuine pregnancy-associated liver injury process.
It is critical to obtain information relating to liver disease risk factors and pre-pregnancy liver status to establish whether any abnormality was present before pregnancy. In general, the earlier in pregnancy that liver abnormality presents, the more likely it is to represent either pre-existing liver disease or non-pregnancy-related acute liver disease. Equally, the best outcome for both mother and baby results from optimising the physical condition of the mother, and in situations of deteriorating liver function (which can be steep in late pregnancy) consideration should always be given to early delivery if the fetus is viable. Joint management between hepatologists and obstetricians is essential.

**Intercurrent and pre-existing liver disease**

Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases and there is no convincing evidence that the mode of delivery affects this. Hepatitis E is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with either worsening or improvement of autoimmune hepatitis, although improvement during pregnancy and rebound post-partum is the most common pattern seen. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones (p. 903) are more common during pregnancy and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made with ultrasound. In biliary obstruction due to gallstones, therapeutic ERCP can be safely performed but lead protection for the fetus is essential and X-ray screening must be kept to a minimum.

**Pregnancy-associated liver disease**

Several conditions occur only during pregnancy, may recur in subsequent pregnancies and resolve after delivery of the baby, and these are discussed on page 1283. The causes of abnormal LFTs in pregnancy, which include pregnancy-associated liver disease, are shown in Box 22.57.

**Liver transplantation**

The outcome following liver transplantation has improved significantly over the last decade so that elective transplantation in low-risk individuals now has a 1-year survival rate of more than 90% and is an effective treatment for end-stage liver disease. The number of procedures is limited by cadaveric donor availability and in many parts of the world this has led to living donor transplant programmes. Despite this, 10% of those listed for liver transplantation will die while awaiting a donor liver. The main complications of liver transplantation relate to rejection, complications of long-term immunosuppression and disease recurrence in the liver graft.

**Indications and contraindications**

Currently, around 9500 liver transplants are undertaken in Europe and the USA annually. About 10% are performed for acute liver failure, 6% for metabolic diseases, 71% for cirrhosis and 11% for hepatocellular carcinoma. Most patients are under 60 years of age and only 10% are aged between 60 and 70 years. Indications for elective transplant assessment are listed in Box 22.58. In North America, the most common indication is hepatitis C cirrhosis, about 10–20% of transplants being for alcoholic cirrhosis (Fig. 22.42). Patients with alcoholic liver disease need to show a capacity for abstinence.

The main contraindications to transplantation are sepsis, extraphepatic malignancy, active alcohol or other substance misuse, and marked cardiorespiratory dysfunction.

Patients are matched for ABO blood group and size but do not require HLA matching with donors, as the liver is a relatively immune-privileged organ compared with the heart or kidneys.

In many parts of the world, the MELD score (see Box 22.30, p. 868) is used to identify and prioritise patients for transplantation. In the UK, a similar system that also incorporates serum sodium, the United Kingdom End-stage Liver Disease (UKELD) score, is used to guide recipient selection. To be listed for elective (non-super-urgent) transplantation in the UK, patients must have a greater than 50% projected post-transplant 5-year survival and must fall into one of three categories:

- **Category 1**: estimated 1-year mortality without transplantation of more than 9% (equivalent to a UKELD score of more than 49 points)

---

**22.57 Abnormal liver function tests in pregnancy**

- **Liver function tests**: alkaline phosphatase (ALP) levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- **Pre-existing liver disease**: pregnancy is uncommon in cirrhosis because cirrhosis causes relative infertility. Varices can enlarge in pregnancy, and ascites should be treated with amiloride rather than spironolactone. Penicillamine for Wilson’s disease and azathioprine for autoimmune liver disease should be continued during pregnancy. Autoimmune liver disease can flare up post-partum.
- **Incidental**: viral, autoimmune and drug-induced hepatitis must be excluded in the presence of an elevated alanine aminotransferase (ALT). Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post-partum, and are a cause of a raised ALP level. Biliary imaging with ultrasound and magnetic resonance cholangiopancreatography is safe. Endoscopic retrograde cholangiopancreatography to remove stones can be performed safely with shielding of the fetus from radiation.
- **Pregnancy-related liver diseases**: occur predominantly in the third trimester and resolve post-partum. Maternal and fetal mortality and morbidity are reduced by expediting delivery.

**22.58 Indications for liver transplant assessment for cirrhosis**

**Complications**

- First episode of bacterial peritonitis
- Diuretic-resistant ascites
- Recurrent variceal haemorrhage
- Hepatocellular carcinoma <5 cm
- Persistent hepatic encephalopathy

**Poor liver function**

- Bilirubin >100 μmol/L (5.8 mg/dL) in primary biliary cholangitis
- MELD score >12 (Box 22.30, p. 868)
- Child–Pugh grade C (Box 22.29, p. 867)

(MELD = Model for End-stage Liver Disease)
Technical complications

These include hepatic artery thrombosis, which may necessitate re-transplantation. Anastomotic biliary strictures can also occur; these may respond to endoscopic balloon dilatation and stenting, or require surgical reconstruction. Portal vein thrombosis is rare.

Rejection

Less immunosuppression is needed following liver transplantation than with kidney or heart/lung grafting. Initial immunosuppression is usually with tacrolimus or ciclosporin, prednisolone and azathioprine or mycophenolate. Some patients can eventually be maintained on a single agent. Acute cellular rejection occurs in 60–80% of patients, commonly at 5–10 days post-transplant and usually within the first 6 weeks, but can arise at any point. This normally responds to 3 days of high-dose intravenous methylprednisolone.

Infections

Bacterial infections, such as pneumonia and wound infections, can occur in the first few weeks after transplantation. Cytomegalovirus (primary infection or reactivation) is a common infection in the 3 months after transplantation and can cause hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk of infection and are usually given prophylactic antiviral therapy, such as valganciclovir. Herpes simplex virus reactivation or, rarely, primary infection may occur. Prophylaxis is given to recipients who have had previous exposure to tuberculosis for the first 6 months after transplantation to prevent reactivation.

Late complications

These include recurrence of the initial disease in the graft and complications due to the immunosuppressive therapy, such as renal impairment from ciclosporin. Metabolic syndrome (p. 730) is common, being described in about 50% of transplant recipients within 6 months in the USA. Chronic vascular rejection is rare, occurring in only 5% of cases.

Prognosis

The outcome following transplantation for acute liver failure is worse than that for chronic liver disease because most patients have multi-organ failure at the time of transplantation. The 1-year survival is 65% and falls only a little to 59% at 5 years. The 1-year survival for patients with cirrhosis is over 90%, falling to 70–75% at 5 years.

Complications

Early complications

Primary graft non-function

This is a state of hepatocellular dysfunction arising as a consequence of liver paresis, which results from ischaemia following removal from the donor and prior to reperfusion in the recipient. Factors that increase the likelihood of primary non-function include increasing donor age, degree of steatosis in the liver and the length of ischaemia. Treatment is supportive until recovery of function. Occasionally, recovery is not seen and re-transplantation is necessary.
**Cholestatic and biliary disease**

The concepts of biliary and cholestatic disease, and the important distinctions between them, can be a source of confusion. ‘Cholestasis’ relates to a biochemical abnormality (typically, elevation of ALP and elevation in serum bile acid levels and bilirubin) that results from an abnormality in bile flow. The cause can range from inherited or acquired dysfunction of transporter molecules responsible for the production of canalicular bile to physical obstruction of the extrahepatic bile duct. ‘Biliary disease’ relates to pathology at any level from the small intrahepatic bile ducts to the sphincter of Oddi. Although there is very significant overlap between cholestatic and biliary disease, there are scenarios where cholestasis can exist without biliary disease (transporter disease or pure drug-induced cholestasis) and where biliary disease can exist without cholestasis (when disease of the bile duct does not impact on bile flow). These anomalies should always be borne in mind and cholestasis and biliary disease always effectively distinguished.

**Chemical cholestasis**

Pure cholestasis can occur as an inherited condition (p. 895), as a consequence of cholestatic drug reactions (p. 894) or as acute cholestasis of pregnancy (p. 1284). A more frequent, but less recognised, acquired biochemical cholestasis occurs in sepsis (‘cholangitis lente’). This biochemical phenomenon is one of the causes of LFT abnormality in sepsis, does not require specific treatment, and has a prognostic significance conferred by the underlying septic process.

Mutations in the biliary transporter proteins on the hepatocyte canalicular membrane (familial intrahepatic cholestasis 1, FIC1), illustrated in Figure 22.7 (p. 851), have been shown to cause an inherited intrahepatic biliary disease in childhood, characterised by raised ALP levels and progression to a biliary cirrhosis. It is also becoming increasingly clear that these proteins contribute to intrahepatic biliary disease in adulthood.

**Benign recurrent intrahepatic cholestasis**

This rare condition usually presents in adolescence and is characterised by recurrent episodes of cholestasis, lasting 1–6 months. It is now known to be mediated by mutations in the ATP8B1 gene, which lies on chromosome 18 and encodes FIC1.

Episodes start with pruritus, while painless jaundice develops later. LFTs show a cholestatic pattern. Liver biopsy shows cholestasis during an episode but is normal between episodes. Treatment is required to relieve the symptoms of cholestasis, such as pruritus, and the long-term prognosis is good.

**Intrahepatic biliary disease**

**Inflammatory and immune disease**

The small intrahepatic bile ducts appear to be specifically vulnerable to immune injury, and ductopenic injury (‘vanishing bile duct syndrome’) can be a feature of a number of chronic conditions, including graft-versus-host disease (GVHD), sarcoidosis and, in the setting of liver transplantation, ductopenic rejection. Intrahepatic small bile duct injury occurs most frequently in primary biliary cholangitis, an autoimmune cholestatic disease, and less frequently in primary sclerosing cholangitis (Box 22.60).

**Carol’s disease**

This very rare disease is characterised by segmental saccular dilatations of the intrahepatic biliary tree. The whole liver is usually affected and extrahepatic biliary dilatation occurs in about one-quarter of patients. Recurrent attacks of cholangitis (see Box 22.18, p. 861) may cause hepatic abscesses. Complications include biliary stones and cholangiocarcinoma. Antibiotics are required for episodes of cholangitis. Occasionally, localised disease can be treated by segmental liver resection, and liver transplantation may sometimes be required.

**Congenital hepatic fibrosis**

This is characterised by broad bands of fibrous tissue linking the portal tracts in the liver, abnormalities of the interlobular bile ducts and sometimes a lack of portal venules. The renal tubules may show cystic dilatation (medullary sponge kidney; p. 433), and eventually renal cysts may develop. The condition can be inherited as an autosomal recessive trait. Liver involvement causes portal hypertension with splenomegaly and bleeding from oesophageal varices that usually presents in adolescence or in early adult life. The prognosis is good because liver function is preserved. Treatment may be required for variceal bleeding and occasionally cholangitis. Patients can present during childhood with renal failure if the kidneys are severely affected.

**Cystic fibrosis**

Cystic fibrosis (p. 580) is associated with biliary cirrhosis in about 5% of individuals. Splenomegaly and an elevated ALP are characteristic. Complications do not normally arise until late adolescence or early adulthood, when bleeding due to variceal haemorrhage may occur. UDCA improves liver blood tests but it is not known whether the drug can prevent progression of liver disease. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of both biliary and pancreatic disease.

**Extrahepatic biliary disease**

Diseases of the extrahepatic biliary tree typically present with the clinical features of impaired bile flow (obstructive jaundice and fat...

22

cholesterol, fat, total calories and refined carbohydrate or lack of dietary fibre has been implicated.

Pathophysiology

Gallstones are conventionally classified into cholesterol or pigment stones, although the majority are of mixed composition. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which are radio-opaque. Gallstone formation is multifactorial and the factors involved are related to the type of gallstone (Boxes 22.61 and 22.62).

Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease, the liver produces bile that contains an excess of cholesterol because there is either a relative deficiency of bile salts or a relative excess of cholesterol (‘lithogenic’ bile). Abnormalities of bile salt synthesis and circulation, cholesterol secretion and gallbladder function may make production of lithogenic bile more likely.

Pigment stones

Brown, crumbly pigment stones are almost always the consequence of bacterial or parasitic biliary infection. They are common in the Far East, where infection allows bacterial β-glucuronidase to hydrolyse conjugated bilirubin to its free form, which cannot be solubilised by bile salts.
which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in developed countries is not satisfactorily explained. Haemolysis is important as a contributing factor for the development of black pigment stones that occur in chronic haemolytic disease.

**Biliary sludge**

This describes gelatinous bile that contains numerous microspheroliths of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

**Clinical features**

Only 10% of individuals with gallstones develop clinical evidence of gallstone disease. Symptomatic stones within the gallbladder (Box 22.63) manifest as either biliary pain (‘biliary colic’) or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term ‘biliary colic’ is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic. Typically, the pain occurs suddenly and persists for about 2 hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20%) and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrathoracic disease, oesophagitis, myocardial infarction or dissecting aortic aneurysm.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as ‘gallstone dyspepsia’. These symptoms are not now recognised as being caused by gallstones and are best regarded as functional dyspepsia (p. 779). Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing ‘limey’ bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of ‘porcelain’ gallbladder results.

Gallstones in the gallbladder (cholechololithiasis) migrate to the common bile duct (choledocholithiasis; p. 906) in approximately 15% of patients and cause biliary colic. Rarely, fistulae develop between the gallbladder and the duodenum, colon or stomach. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may impact either at the terminal ileum or occasionally in the duodenum or sigmoid colon. The resultant intestinal obstruction may be followed by ‘gallstone ileus’. Gallstones impacted in the cystic duct may cause strictureting of the common hepatic duct and the clinical picture of extrahepatic biliary diseases (‘Mirizzi’s syndrome’, with its important differential of malignant bile duct stricture). The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due (it is thought) to oedema at the ampulla as the stone passes into the duodenum (no stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage). Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease (it may present with jaundice, obstructive LFTs with biliary dilatation, post-cholecystectomy pain or acute pancreatitis).

Cancer of the gallbladder is growing in frequency (p. 907) but in over 95% of cases is associated with the presence of gallstones. Previously, the diagnosis was typically made as an incidental histological finding following cholecystectomy for gallstone disease. Increasing awareness of the risk of gallbladder carcinoma and of the role played by polyps in the natural history has led to an increase in screening activity and prospective diagnosis.

**Investigations**

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has more than 92% sensitivity and 99% specificity for gallbladder stones (see Fig. 22.8, p. 854). CT, MRCP (Fig. 22.44) and, increasingly, EUS are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema) but are inferior to ultrasound in defining
May arise.

Perforation occurs in 10–15% of cases and gallbladder empyema or even stricturing of the common bile duct following stone passage of stones into the common bile duct, or to compression of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a biliary tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage, which releases phospholipase, converting biliary lecithin to lysolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in elderly patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

**Management**

Asymptomatic gallstones found incidentally should not be treated because the majority will never cause symptoms. Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy; the severity of symptoms should be balanced against the individual patient surgical risk in order to decide whether surgery is warranted. Various techniques can be used to treat common bile duct stones (Box 22.64).

**Cholecystitis**

**Acute cholecystitis**

**Pathophysiology**

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a biliary tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage, which releases phospholipase, converting biliary lecithin to lysolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in elderly patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

**Clinical features**

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic (p. 904) and acute cholecystitis may be difficult; features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness, rigidity worse on inspiration (Murphy’s sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual. Jaundice occurs in less than 10% of patients and is usually due to passage of stones into the common bile duct, or to compression or even strictureting of the common bile duct following stone impaction in the cystic duct (Mirizzi’s syndrome). Gallbladder perforation occurs in 10–15% of cases and gallbladder empyema may arise.

**Investigations**

Peripheral blood leucocytosis is common, except in the elderly patient, in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis (p. 837), which may be a potentially serious complication of gallstones. Only when the amylase is higher than 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur with many other causes of abdominal pain. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intraabdominal gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis but gallbladder empyema or perforation is best assessed by CT.

**Management**

**Medical**

Medical management consists of bed rest, pain relief, antibiotics and intravenous fluids. Moderate pain can be treated with NSAIDs but more severe pain should be managed with opiates. A cephalosporin (such as cefuroxime) or piperacillin/tazobactam is the usual antibiotic of choice, but metronidazole is normally added in severely ill patients and local prescribing practice may vary. Nasogastric aspiration is needed only for persistent vomiting. Cholecystitis usually resolves with medical treatment but the inflammation may progress to an empyema or perforation and peritonitis.

**Surgical**

Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. Operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. When cholecystectomy may be difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

**Chronic cholecystitis**

Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often at night and following a heavy meal. The clinical features are similar to those of acute calculous cholecystitis but milder. Patients may recover spontaneously or following analgesia and antibiotics. They are usually advised to undergo elective laparoscopic cholecystectomy.

**Acute cholangitis**

Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems, such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, fever (with or without rigors) and right upper quadrant pain are the main presenting features (“Charcot’s triad”). Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.
cause of the obstruction in the common bile duct; 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. EUS is extremely accurate at identifying bile duct stones. MRCP is non-invasive and is indicated when intervention is not necessarily mandatory (e.g., the patient with possible bile duct stones but no jaundice or sepsis).

Management
Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics, such as cefuroxime and metronidazole (local prescribing practice may vary). Blood cultures should be taken before the antibiotics are administered. Patients also require urgent decompression of the biliary tree and stone removal. ERCP with biliary sphincterotomy and stone extraction is the treatment of choice and is successful in about 90% of patients. If ERCP fails, other approaches include percutaneous transhepatic drainage and combined (‘rendezvous’) endoscopic procedures, extracorporeal shock wave lithotripsy (ESWL) and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP, and before the common bile duct is explored the diagnosis of choledocholithiasis should be confirmed by intraoperative cholangiography. If gallstones are found, the bile duct is explored, either via the cystic duct or by opening it, all stones are removed, clearance is checked by cholangiography or choledochoscopy, and then primary closure of the duct is performed if possible. External drainage of the common bile duct by T-tube is rarely required nowadays. It is now possible to achieve these goals laparoscopically in specialist centres.

Recurrent pyogenic cholangitis
This disease occurs predominantly in South-east Asia. Biliary sludge, calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage and requires
Tumours of the gallbladder and bile duct

Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually in those over the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder (‘porcelain gallbladder’; p. 904) are at high risk of malignant change, and gallbladder polyps over 1 cm in size are associated with increased risk of malignancy; preventative cholecystectomy should be considered in such patients. Chronic infection with Salmonella, especially in areas where typhoid is endemic, is also a risk factor.

Carcinoma of the gallbladder may be diagnosed incidentally and is found in 1–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and, later, persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and porcelain gallbladder may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is invariable and palliative management is usually all that can be offered. Survival is generally short, death typically occurring within 1 year in patients presenting with symptoms.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is an uncommon tumour that can arise anywhere in the biliary tree, from the intrahepatic bile ducts (20–25% of cases) and the confluence of the right and left hepatic ducts at the liver hilum (50–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the incidence is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli’s disease and choledochal cysts (see Fig. 22.43). In the Far East, particularly northern Thailand, chronic liver fluke infection (Clonorchis sinensis) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of approximately 20%, although only 5% of CCAs relate to primary sclerosing cholangitis. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths. The presentation is usually with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made using a combination of CT and MRI (see Fig. 22.10, p. 855) but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19-9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. Endoscopic ultrasound–fine needle aspiration (EUS-FNA) of bile duct masses is sometimes possible, and in specialist centres single-operator cholangioscopy with biopsy is now established. CCA can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. However, most patients are treated by stent insertion across the malignant biliary stricture, using endoscopic or percutaneous transhepatic techniques (Fig. 22.47). Combination chemotherapy is increasingly used and palliation with endoscopic photodynamic therapy has provided encouraging results.

Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relationship to the ampulla of Vater and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour but staging by CT/MRI and EUS is essential. Ampullary carcinoma must be differentiated from carcinoma of drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.
the head of the pancreas and a CCA because these last two conditions both have a worse prognosis. Imaging may show a ‘double duct sign’ with strictureting of both the common bile duct and pancreatic duct at the ampulla and upstream dilatation of the ducts. The diagnosis is established by excluding gallstones, including microlithiasis, and by demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry. This is not widely available, however, and is associated with a high rate of procedure-related pancreatitis. Hepatobiliary scintigraphy (e.g., hepatobiliary iminodiacetic acid) may have value in the second-line investigation of post-cholecystectomy syndrome.

### Functional biliary sphincter disorders (‘sphincter of Oddi dysfunction’)

The sphincter of Oddi is a small smooth-muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. It has been believed that sphincter of Oddi dysfunction (SOD) was characterised by an increase in contractility that produces a benign non-calculous obstruction to the flow of bile or pancreatic juice. This may cause pancreaticobiliary pain, deranged LFTs or recurrent pancreatitis. Classification systems, based on clinical history, laboratory results, findings on investigation and response to interventions, are difficult because of the fluctuating nature of symptoms and the well-recognised placebo effect of interventions. SOD was previously classified into types I–III but these have been replaced by newer terminology (Boxes 22.66 and 22.67).

### Clinical features

Patients with functional biliary sphincter disorders, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease:

- **Patients with biliary sphincter disorders experience** recurrent, episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.

- **Patients with pancreatic sphincter disorders usually present with unexplained recurrent attacks of pancreatitis.**

### Investigations

The diagnosis is established by excluding gallstones, including microolithiasis, and by demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry. This is not widely available, however, and is associated with a high rate of procedure-related pancreatitis. Hepatobiliary scintigraphy (e.g., hepatobiliary iminodiacetic acid) may have value in the second-line investigation of post-cholecystectomy syndrome.

Adenomyomatosis of the gallbladder

In this condition, there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitansky–Aschoff sinuses. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It may be diagnosed by oral cholecystography, when a halo or ring of opacified diverticula can be seen around the gallbladder. Other appearances include deformity of the body of the gallbladder or marked irregularity of the outline. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a ‘Phrygian cap’. Most patients are treated by cholecystectomy but only after other diseases in the upper gastrointestinal tract have been excluded.

IgG4-associated cholangitis

This recently reported disease often presents with obstructive jaundice and is described on page 890.

Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities must include a general history and examination, as well as a search for symptoms and signs of abnormalities of red cells, white cells, platelets, haemostatic systems, lymph nodes and lymphoreticular tissues.

### Lymphadenopathy

Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.

#### History
- Speed of onset, rate of enlargement
- Painful or painless
- Associated symptoms: weight loss, night sweats, itch

#### Examination
- Sites: localised, generalised
- Size (cm)
- Character: hard, soft, rubbery
- Fixed, mobile
- Search area that node drains for abnormalities (e.g. dental abscess)
- Other general examination (e.g. joints, rashes, finger clubbing)

### Anaemia

Symptoms and signs help to indicate the clinical severity of anaemia. A full history and examination is needed to identify the underlying cause.

#### Non-specific symptoms
- Tiredness
- Lightheadedness
- Breathlessness
- Development/worsening of ischaemic symptoms, e.g. angina or claudication

#### Non-specific signs
- Mucous membrane pallor
- Tachypnoea
- Raised jugular venous pressure
- Tachycardia
- Flow murmurs
- Ankle oedema
- Postural hypotension

### Bleeding

Bleeding can be due to congenital or acquired abnormalities in the clotting system. History and examination help to clarify the severity and the underlying cause of the bleeding problem.

#### History
- Site of bleed
- Duration of bleed
- Precipitating causes, including previous surgery or trauma
- Family history
- Drug history
- Age at presentation
- Other medical conditions, e.g. liver disease

#### Examination

There are two main patterns of bleeding:
1. Mucosal bleeding
   - Reduced number or function of platelets (e.g. bone marrow failure or aspirin) or von Willebrand factor (e.g. von Willebrand disease)
   - Skin: petechiae, bruises
   - Gum and mucous membrane bleeding
   - Fundal haemorrhage
   - Post-surgical bleeding
2. Coagulation factor deficiency
   - (e.g. haemophilia or warfarin/anticoagulant)
   - Bleeding into joints (haemarthrosis) or muscles
   - Bleeding into soft tissues
   - Retroperitoneal haemorrhage
   - Intracranial haemorrhage
   - Post-surgical bleeding

### Examination of the spleen

- Move your hand up from the right iliac fossa, towards the left upper quadrant on expiration.
- Keep your hand still and ask the patient to take a deep breath through the mouth to feel the spleen edge being displaced downwards.
- Place your left hand around the patient’s lower ribs and approach the costal margin to pull the spleen forwards.
- To help palpate small spleens, roll the patient on to the right side and examine as before.

#### Characteristics of the spleen
- Notch
- Superficial
- Dull to percussion
- Cannot get examining hand between ribs and spleen
- Moves well with respiration
Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting humans (anaemias) to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur as a consequence of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

**Functional anatomy and physiology**

Blood flows throughout the body in the vascular system, and consists of:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which defend against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding
- plasma, which contains proteins with many functions, including antibodies and coagulation factors.

**Haematopoiesis**

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the yolk sac, liver and spleen, and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow) so that, in adults, normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red marrow can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made up of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 23.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and also phagocytoses nuclei from red cells prior to their release into the circulation. Megakaryocytes are large cells that produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells that normally represent less than 5% of the marrow population and are scattered throughout the intertrabecular spaces.

**Stem cells**

All blood cells are derived from pluripotent haematopoietic stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e. make more stem cells) or differentiate to produce a hierarchy of lineage-committed progenitor cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU–GM (colony-forming unit – granulocyte, monocyte) is a progenitor cell that produces granulocytic and monocytic lines, CFU–E produce erythroid cells, and CFU–Meg produce megakaryocytes and ultimately platelets (Fig. 23.2).

Growth factors, produced in bone marrow stromal cells and elsewhere, control the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as, interleukin-3 (IL–3), stem cell factor (SCF) and granulocyte, macrophage–colony-stimulating factor (GM–CSF), act on a wide number of cell types at various stages of differentiation. Others, such as erythropoietin, granulocyte–colony-stimulating factor (G–CSF) and thrombopoietin (Tpo), are lineage-specific. Many of these growth factors are now synthesised by recombinant DNA technology and used as treatments: for example, erythropoietin to correct renal anaemia and G–CSF to hasten neutrophil recovery after chemotherapy.

The bone marrow also contains stem cells that can differentiate into non-haematological cells. Mesenchymal stem cells differentiate
deformable, with a lipid bilayer to which a ‘skeleton’ of filamentous proteins is attached via special linkage proteins (Fig. 23.4).

Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 23.8D). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 23.4). The ABO and Rhesus systems are the most commonly recognised (p. 931) but over 400 blood group antigens have been described.

Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A (αα/ββ) represents over 90% of adult haemoglobin, whereas haemoglobin F (αα/γγ) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe^{2+}), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains ‘swing’ closer together; they move apart as oxygen is lost. In the ‘open’ deoxygenated state, 2,3-bisphosphoglycerate (2,3-BPG), a product of red cell metabolism, increases the affinity for oxygen and favours the release of oxygen to the tissues.

Blood cells and their functions

Red cells

Red cell precursors formed in the bone marrow from the erythroid (CFU–E) progenitor cells are called erythroblasts or normoblasts (Fig. 23.3). These divide and acquire haemoglobin, which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte, which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge (‘polychromasia’). Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by erythropoietin, a polypeptide hormone produced by renal interstitial peritubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure (p. 384) causes anaemia, which can be treated with exogenous recombinant erythropoietin or similar pharmacological agents called erythropoiesis-stimulating agents, e.g. darbepoetin.

Normal mature red cells circulate for about 120 days. They are 8 μm biconcave discs lacking a nucleus but filled with haemoglobin, which delivers oxygen to the tissues. In order to pass through the smallest capillaries, the red cell membrane is deformable, with a lipid bilayer to which a ‘skeleton’ of filamentous proteins is attached via special linkage proteins (Fig. 23.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 23.8D). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 23.4). The ABO and Rhesus systems are the most commonly recognised (p. 931) but over 400 blood group antigens have been described.

Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A (αα/ββ) represents over 90% of adult haemoglobin, whereas haemoglobin F (αα/γγ) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe^{2+}), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains ‘swing’ closer together; they move apart as oxygen is lost. In the ‘open’ deoxygenated state, 2,3-bisphosphoglycerate (2,3-BPG), a product of red cell metabolism, increases the affinity for oxygen and favours the release of oxygen to the tissues.
Fig. 23.3 Maturation pathway of red cells, granulocytes and platelets. The image on the right is a normal blood film.

Fig. 23.4 Normal structure of red cell membrane. Red cell membrane flexibility is conferred by attachment of cytoskeletal proteins. Important transmembrane proteins include band 3 (an ion transport channel) and glycophorin C (involved in cytoskeletal attachment and gas exchange, and a receptor for Plasmodium falciparum in malaria). Antigens on the red blood cell determine an individual’s blood group. There are about 22 blood group systems (groups of carbohydrate or protein antigens controlled by a single gene or by multiple closely linked loci); the most important clinically are the ABO and Rhesus (Rh) systems (p. 931). The ABO genetic locus has three main allelic forms: A, B and O. The A and B alleles encode glycosyltransferases that introduce N-acetylgalactosamine (open circle) and D-galactose (blue circle), respectively, on to antigenic carbohydrate molecules on the membrane surface. People with the O allele produce an O antigen, which lacks either of these added sugar groups. Rh antigens are transmembrane proteins.

metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 23.5). The position of this curve depends on the concentrations of 2,3-BPG, H⁺ ions and CO₂; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g. when red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3-BPG and has a left-shifted oxygen dissociation curve, which, together with the low pH of fetal blood, ensures fetal oxygenation. Strong oxidising agents, such as dapsone, can convert ferrous iron in haemoglobin to its ferric state (Fe³⁺). The resultant methaemoglobin also has a left-shifted oxygen dissociation curve, which can result in tissue hypoxia (p. 135).

Genetic mutations affecting the haem-binding pockets of globin chains or the ‘hinge’ interactions between globin chains result in haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16, and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains results in the thalassaemias (p. 951). Defects in haem synthesis cause the porphyrias (p. 378).
Functional anatomy and physiology • 917

Fig. 23.5 The haemoglobin-oxygen dissociation curve. Factors are listed that shift the curve to the right (more oxygen released from blood) and to the left (less oxygen released at given PO₂). To convert kPa to mmHg, multiply by 7.5. (2,3-BPG = 2,3-bisphosphoglycerate)

**Destruction**
Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for reuse in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

**White cells**
White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 23.12). Granulocytes and monocytes are formed from bone marrow CFU–GM progenitor cells during myelopoiesis. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleolus. As the cells divide and mature, the nucleus segments and the cytoplasm acquires specific neutrophilic, eosinophilic or basophilic granules (see Fig. 23.3). This takes about 14 days. The cytokines G–CSF, GM–CSF and M–CSF are involved in the production of myeloid cells, and G–CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally found only in the marrow but may appear in the circulation in infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a ‘leucoerythroblastic’ picture; this indicates a serious disturbance of marrow function.

**Neutrophils**
Neutrophils, the most common white blood cells in the blood of adults, are 10–14 μm in diameter, with a multilobular nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (p. 64). A large storage pool of mature neutrophils exists in the bone marrow. Every day, some 10¹¹ neutrophils enter the circulation, where cells may be circulating freely or attached to endothelium in the marginal pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in the circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

**Eosinophils**
Eosinophils represent 1–6% of the circulating white cells. They are a similar size to neutrophils but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (p. 233). They are also involved in allergic reactions (e.g. atopic asthma, p. 567; see also p. 84).

**Basophils**
These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules that obscure the nucleus. Mast cells resemble basophils but are found only in the tissues. These cells are involved in hypersensitivity reactions (p. 66).

**Monocytes**
Monocytes are the largest of the white cells, with a diameter of 12–20 μm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into tissue, where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1, p. 64).

**Lymphocytes**
Lymphocytes are derived from pluripotent haematopoietic stem cells in the bone marrow. There are two main types: T cells (which mediate cellular immunity) and B cells (which mediate humoral immunity) (p. 68). Lymphoid cells that migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow. The majority (about 80%) of lymphocytes in the circulation are T cells. Lymphocytes are heterogeneous, the smallest being the size of red cells and the largest the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm but the larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations have specific functions and lifespan can vary from a few days to many years. Cell surface antigens (‘cluster of differentiation’ (CD) antigens), which appear at different points of lymphocyte maturation and indicate the lineage and maturity of the cell, are used to classify lymphomas and lymphoid leukaemias.

**Haemostasis**
Blood must be maintained in a fluid state in order to function as a transport system, but must be able to solidify to form a clot following vascular injury in order to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis
is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets, von Willebrand factor, coagulation factors, natural anticoagulants and fibrinolytic enzymes (Fig. 23.6). Dysfunction of any of these components may result in haemorrhage or thrombosis.

**Platelets**

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic progenitor cells (CFU–Meg) divide to form megakaryoblasts, which undergo a process called ‘endomitotic reduplication’, in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Large numbers of platelets then fragment off from each megakaryocyte into the circulation. The formation and maturation of megakaryocytes is stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the reticuloendothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.

Under normal conditions, platelets are discoid, with a diameter of 2–4 μm (Fig. 23.7). The surface membrane invaginates to form a tubular network, the canalicular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs that inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopidogrel, prasugrel and ticagrelor (adenosine diphosphate (ADP)-mediated activation inhibitors), dipyridamole (phosphodiesterase inhibitor), and the glycoprotein IIb/IIIa inhibitors abciximab, tirofiban and eptifibatide (which prevent fibrinogen binding; p. 500).

**Clotting factors**

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman numerals.
When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix ‘a’. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways: it is initiated by the extrinsic (or tissue factor) pathway and amplifies by the ‘intrinsic pathway’ (see Fig. 23.6D).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow them to participate in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase enzyme is activated by warfarin, and this is the basis of the anticoagulant effect of coumarins (p. 939). Congenital (e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.

**Investigation of diseases of the blood**

**The full blood count**

To obtain a full blood count (FBC), anticoagulated blood is processed through automated blood analysers that use a variety of technologies (particle-sizing, radiofrequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices that give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a

**Fig. 23.6, cont’d** fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see E and F).

**E** Stage 4. Limiting clot formation: natural anticoagulants reverse activation of coagulation factors. Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as Xa, X and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates Xa and X. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor, protein S (PS), and cleaves Va and VIIIa. PC and PS are vitamin K-dependent and are depleted by coumarin anticoagulants such as warfarin.

**E** Stage 5. Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair. The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (t-PA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products, including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by α2-antiplasmin and α2-macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.

The reference ranges for a number of common haematological parameters in adults are given in Chapter 35.

Blood film examination

Although technical advances in full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the ‘blood film’) can often yield valuable information (Box 23.2 and Fig. 23.8). Analysers cannot identify abnormalities of red cell shape and content (e.g. Howell–Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

Bone marrow examination

In adults, bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow can be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 23.9). A bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome and molecular studies to assess malignant disease, or marrow culture for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow fibrosis, and infiltration by abnormal cells such as metastatic carcinoma.

Investigation of coagulation

Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 913), there are recommended screening tests (Box 23.3). Physiological activation of coagulation is predominantly by tissue factor, with amplification of the process by the small amounts of thrombin formed as a result. For ease of description, the terms extrinsic, intrinsic and common pathways are still used (see Fig. 23.6D). Coagulation tests measure the time to clot formation in vitro in a plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The tissue factor (‘extrinsic’) pathway (see Fig. 23.6D) is assessed by the prothrombin time (PT), and the ‘intrinsic’ pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin (PTTK). Coagulation is delayed by deficiencies of coagulation factors and by the presence of inhibitors of coagulation, such as heparin. The approximate reference ranges and causes of abnormalities are shown in Box 23.3. If both the PT and APTT are prolonged, this indicates either deficiency or inhibition of the
Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin, arachidonic acid and ADP, agglutination in response to ristocetin or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate, adenosine diphosphate and their ratio to each other (ATP/ADP).

Coagulation screening tests are also performed in patients with suspected DIC, when clotting factors and platelets are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with final common pathway (which includes factors X, V, prothrombin and fibrinogen) or global coagulation factor deficiency involving more than one factor, as occurs in disseminated intravascular coagulation (DIC, pp. 196 and 973). Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be a chemical (heparins) or an antibody (most often a lupus anticoagulant but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 974.

Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin, arachidonic acid and ADP, agglutination in response to ristocetin or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate, adenosine diphosphate and their ratio to each other (ATP/ADP). Coagulation screening tests are also performed in patients with suspected DIC, when clotting factors and platelets are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with...
INR is the ratio of the patient’s PT to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by comparison with an international reference standard material). Concentrations of the direct oral anticoagulants (DOACs) cannot be accurately assessed from the PT or the APTT, with which they have a variable and generally poor correlation.

Monitoring of heparin therapy is, on the whole, required only with unfractionated heparins. Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of approximately 1.5–2.5. Low-molecular-weight heparins have such a predictable dose response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (glomerular filtration rate less than 30 mL/min). When monitoring is indicated, an anti-Xa activity assay rather than APTT should be used.

**Thrombotic disorders**

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active venous thrombosis in some patients (see Fig. 10.6, p. 187).

A variety of tests exist that may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (thrombophilia) (Box 23.4). Examples of possible indications for testing are given in Box 23.5. In most patients, the results do not affect clinical management (p. 975) but they may influence the duration of anticoagulation (e.g. antiphospholipid antibodies, p. 977), justify family screening in inherited thrombophilias (p. 975), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 950). Anticoagulants can interfere with some of these assays; for example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant, while heparin interferes with antithrombin and lupus anticoagulant.
Anaemia refers to a state in which the level of haemoglobin in the blood is below the reference range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must be taken into account when considering whether an individual is anaemic. The clinical features of anaemia reflect diminished oxygen supply to the tissues (p. 912). A rapid onset of anaemia (e.g. due to blood loss) causes more profound symptoms than a gradually developing anaemia. Individuals with cardiorespiratory disease are more susceptible to symptoms of anaemia.

The clinical assessment and investigation of anaemia should gauge its severity and define the underlying cause (Box 23.7).

### Clinical assessment

- **Iron deficiency anaemia** (p. 940) is the most common type of anaemia worldwide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia is a common cause of anaemia in pre-menopausal females, so women should always be asked about their periods.
- A dietary history should assess the intake of iron and folate, which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; pp. 712, 945 and 1284).
- Past medical history may reveal a disease that is known to be associated with anaemia, such as rheumatoid arthritis (anaemia of chronic disease), or previous surgery (e.g. resection of the stomach or small bowel, which may lead to malabsorption of iron and/or vitamin B₁₂).  
- Family history and ethnic background may raise suspicion of haemolytic anaemias, such as the haemoglobinopathies and hereditary spherocytosis. Pernicious anaemia may also run in families but is not associated with a clear Mendelian pattern of inheritance.
- A drug history may reveal the ingestion of drugs that cause blood loss (e.g. aspirin and anti-inflammatory drugs), haemolysis (e.g. sulphonamides) or aplasia (e.g. chloramphenicol).

On examination, as well as the general physical findings of anaemia shown on page 912, there may be specific findings related to the aetiology of the anaemia; for example, a patient may be found to have a right iliac fossa mass due to an underlying caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B₁₂ deficiency may be associated with neurological signs, including peripheral neuropathy, dementia and signs of subacute combined degeneration of the cord (p. 1139). Sickle-cell anaemia (p. 951) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia may be multifactorial and the lack of specific symptoms and signs does not rule out silent pathology.

### Investigations

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:
Fig. 23.10 Investigation of anaemia with normal or low mean cell volume (MCV). (Hb = haemoglobin; MCH = mean cell haemoglobin)

Fig. 23.11 Investigation of anaemia with high mean cell volume (MCV). (LDH = lactate dehydrogenase)
• A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease, also known as the anaemia of inflammation (ACD/AI) (Fig. 23.10).
• A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia or sometimes ACD/AI (Fig. 23.10).
• A high MCV (macrocytic anaemia) suggests vitamin B₁₂ or folate deficiency or myelodysplasia (Fig. 23.11).

Specific types of anaemia and their management are described later in this chapter (p. 940).

**High haemoglobin**

Patients with a persistently raised haematocrit (Hct) (>0.52 males, >0.48 females) for more than 2 months should be investigated. “True” polycythaemia (or absolute erythrocytosis) indicates an excess of red cells, while ‘relative’, ‘apparent’ or ‘low-volume’ polycythaemia is due to a decreased plasma volume. Causes of polycythaemia are shown in Box 23.8. These involve increased erythropoiesis in the bone marrow, either due to a primary increase in marrow activity, or in response to increased erythropoietin (Epo) levels in chronic hypoxiaemia, or due to inappropriate secretion of Epo. Athletes who seek to benefit from increased oxygen-carrying capacity have been known to use Epo to achieve this.

Apparent erythrocytosis with a raised Hct, normal red cell mass (RCM) and reduced plasma volume may be associated with hypertension, smoking, alcohol and diuretic use (Gaisböck’s syndrome).

**Clinical assessment and investigations**

Males and females with Hct values of over 0.60 and over 0.56, respectively, can be assumed to have an absolute erythrocytosis. A clinical history and examination will identify most patients with polycythaemia secondary to hypoxia. The presence of hypertension, smoking, excess alcohol consumption and/or diuretic use is consistent with low-volume polycythaemia (Gaisböck’s syndrome). In polycythaemia rubra vera (PRV), a mutation in a kinase, JAK-2 V617F, is found in over 90% of cases (p. 970). Patients with PRV have an increased risk of arterial thromboses, particularly stroke, and venous thromboembolism. They may also have aquagenic pruritus (itching after exposure to water), hepatosplenomegaly and gout (due to high red cell turnover).

If the JAK-2 mutation is absent and there is no obvious secondary cause, a measurement of red cell mass is required to confirm an absolute erythrocytosis, followed by further investigations to exclude hypoxia, and causes of inappropriate erythropoietin secretion.

**Leucopenia (low white cell count)**

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types (usually neutrophils or lymphocytes).

Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 930).

**Neutropenia**

A reduction in neutrophil count (usually <1.5×10⁹/L but dependent on age and race) is called neutropenia. The main causes are listed in Box 23.9 and Figure 23.12. Drug-induced neutropenia is not uncommon (Box 23.10). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than 0.5×10⁹/L considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy is not commenced. Management is discussed on page 224.

**Lymphopenia**

This is an absolute lymphocyte count of less than 1×10⁹/L. The causes are shown in Box 23.9. Although minor reductions may be asymptomatic, deficiencies in cell-mediated immunity may result in infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as Epstein-Barr virus (EBV), human papillomavirus (HPV))

and human herpesvirus 8 (HHV-8)). Lymphopenia without any obvious cause is common with advancing age.

### Leucocytosis (high white cell count)

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see Box 23.9). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not increase the total white cell count (WCC) above the upper limit of normal and will be apparent only if the ‘differential’ of the white count is examined.

#### Neutrophilia

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends on age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils but also earlier forms, such as metamyelocytes, can be found in the blood. The causes of a neutrophilia are shown in Box 23.9.

#### Basophilia

- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn’s disease
- Iron deficiency

#### Monocytosis

- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn’s disease
- Malignancy: solid tumours, chronic myelomonocytic leukaemia

#### Lymphocytosis

- Infection: viral, bacterial (e.g. *Bordetella pertussis*)
- Lymphoproliferative disease: chronic lymphocytic leukaemia, lymphoma
- Post-splenectomy

#### Lymphopenia

- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: glucocorticoids, cytotoxics
- Congenital: severe combined immunodeficiency
- HIV infection
Eosinophilia

A high eosinophil count of more than 0.5 $\times 10^9$/L is usually secondary to infection (especially parasites; p. 233), allergy (e.g. eczema, asthma, reactions to drugs; p. 84), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see Box 23.9). Usually, such eosinophilia is short-lived.

In the rarer primary disorders, there is a persistently raised, often clonal, eosinophilia, e.g. in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hypereosinophilic syndrome (HES). Recently, specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing rearrangements of platelet-derived growth factor receptors $\alpha$ and $\beta$ or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib.

Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); evaluation of eosinophilia therefore includes not only the identification of any underlying cause and its appropriate treatment but also assessment of any related organ damage.

Lymphocytosis

A lymphocytosis is an increase in circulating lymphocytes above that expected for the patient’s age. In adults, this is greater than 3.5 $\times 10^9$/L. Infants and children have higher counts; age-related reference ranges should be consulted. Causes are shown in Box 23.9; the most common is viral infection.

Lymphadenopathy

Enlarged lymph glands may be an important indicator of haematological disease but they are not uncommon in reaction to infection or inflammation (Box 23.11). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 913. Nodes that enlarge in response to local infection or inflammation (‘reactive nodes’) usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation or primary malignancy in the appropriate drainage area:

- the scalp, ear, mouth and throat, face, teeth or thyroid for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes.

Generalised lymphadenopathy may be secondary to infection, often viral, connective tissue disease or extensive skin disease (dermatopathic lymphadenopathy) but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats that may require a change of nightclothes are associated with haematological malignancies, particularly lymphoma.

Initial investigations in lymphadenopathy include an FBC (to detect neutrophilia in infection or evidence of haematological disease), measurement of erythrocyte sedimentation rate (ESR) and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision biopsy of a representative node is indicated to obtain a histological diagnosis.

Splenomegaly

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extramedullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections, or vascular congestion as a result of portal hypertension (Box 23.12). Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating and early satiety due to stomach compression. Splenic infarction produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation should focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen, which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis, as might a bone marrow biopsy in splenic lymphomas. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leucoerythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease (p. 852) may be appropriate. If all investigations are unhelpful, splenectomy may be diagnostic but is rarely carried out in these circumstances.

Bleeding

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, the coagulation factors or von Willebrand factor, or...
bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent bleeds at a single site suggest a local structural abnormality rather than coagulopathic bleeding.

- **Duration of history.** It may be possible to assess whether the disorder is congenital or acquired.
- **Precipitating causes.** Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.
- **Surgery.** Ask about operations. Dental extractions, tonsillectomy and circumcision are stressful tests of the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis; delayed haemorrhage is more suggestive of a coagulation defect. However, in post-surgical patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than a bleeding disorder.
- **Family history.** While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history, and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- **Drugs.** Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some ‘herbal’ remedies may result in a bleeding diathesis.

Clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 23.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction.
Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple but become yellow as haemoglobin is degraded. Retroperitoneal bleeding presents with a flank or peri-umbilical haematoma. Telangiectasia of lips and tongue points to hereditary haemorrhagic telangiectasia (p. 970). Joints should be examined for evidence of haemarthroses. A full examination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

**Investigations**
Screening investigations and their interpretation are described on page 920. If the patient has a history that is strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed (p. 921).

### Thrombocytopenia (low platelet count)
A reduced platelet count may arise by one of two mechanisms:
- decreased or abnormal production (bone marrow failure and hereditary thrombocytopenias)
- increased consumption following release into the circulation (immune-mediated, DIC or sequestration).

Spontaneous bleeding does not usually occur until the platelet count falls below $20 \times 10^9/L$, unless their function is also compromised. Purpura and spontaneous bruising are characteristic but there may also be oral, nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia ($<10 \times 10^9/L$) may result in retinal haemorrhage and potentially fatal intracranial bleeding, but this is rare.

Investigations are directed at the possible causes listed in Box 23.14. A blood film is the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts below $10 \times 10^9/L$, or to clinical situations with actual or predicted serious haemorrhage.

### Thrombocytosis (high platelet count)
The most common reason for a raised platelet count is that it is reactive to another process, such as infection, inflammation, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 23.15). The presenting clinical features are usually those of the underlying disorder and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets, lack of splenomegaly, and the presence of an associated disorder. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time (reactive thrombocytosis gets better with resolution of the underlying cause).

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia

### 23.14 Causes of thrombocytopenia

**Haematinic deficiency**
- Vitamin B12, and/or folate deficiency

**Familial (macro-)thrombocytopenies**
- Myosin heavy chain abnormalities, e.g. Alport’s syndrome, Fechtner’s syndrome, May–Hegglin anomaly
- Bernard–Soulier syndrome
- Montreal platelet syndrome
- Wiskott–Aldrich syndrome (small platelets)
- Mediterranean macrothrombocytopeny

**Increased consumption**
- Immune mechanisms
  - Idiopathic thrombocytopenic purpura
  - Neonatal alloimmune thrombocytopenia
- Post-transfusion purpura
- Drug-associated, especially quinine, vancomycin and heparin

**Coagulation activation**
- Disseminated intravascular coagulation (see Box 23.68, p. 978)

**Mechanical pooling**
- Hypersplenism

**Thrombotic microangiopathies**
- Haemolytic uraemic syndrome (HUS) and atypical HUS
- Liver disease

**Others**
- Gestational thrombocytopenia
- Type 2B von Willebrand disease

*Associated conditions include collagen vascular diseases (particularly systemic lupus erythematosus), B-cell malignancy, HIV infection and antiphospholipid syndrome.

**Clonal thrombocytosis**
- Primary thrombocythaemia
- Polycythaemia rubra vera
- Chronic myeloid leukaemia
- Myelofibrosis
- Myelodysplastic syndromes (MDSs: refractory anaemia with ring sideroblasts and thrombocytosis (FAS-T), MDS with isolated deletion of $5q$)
and some forms of myelodysplasia. As with PRV, patients with essential thrombocythaemia may present with thrombosis or, rarely, bleeding. Stroke, transient ischaemic attacks, amaurosis fugax, digital ischaemia or gangrene, aquagenic pruritus, splenomegaly and systemic upset are also features. Patients with myeloproliferative disorders may also present with features such as aquagenic pruritus, splenomegaly and systemic upset.

**Pancytopenia**

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells as a consequence of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in Box 23.16. A bone marrow aspirate and trephine are usually required to establish the diagnosis.

**Infection**

Infection is a major complication of haematological disorders. It relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 224 and 925).

**Blood products**

Blood components are prepared from whole blood or specific blood constituents collected from individual donors and include red cells, platelets, plasma and cryoprecipitate (Box 23.17). Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes of human plasma obtained from many people and treated to remove transmissible infection. Examples include:

- **Coagulation factors.** Concentrates of factors VIII and IX are used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease. Coagulation factors made by recombinant DNA technology are now preferred due to perceived lack of infection risk but plasma-derived products are still used in many countries.
- **Immunoglobulins.** Intravenous immunoglobulin G (IVIgG) is administered as regular replacement therapy to reduce infective complications in patients with primary and secondary immunodeficiency. A short, high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 971) and Guillain–Barré syndrome (p. 1140). IVIgG can cause acute reactions and must be infused strictly according to the manufacturer’s product information. There is a risk of renal dysfunction in susceptible patients and, in these circumstances, immunoglobulin products containing low or no sucrose are preferred. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster (p. 239).
- **Anti-RhE D immunoglobulin** is used in pregnancy to prevent haemolytic disease of the newborn (see Box 23.19 below).
- **Human albumin.** This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid but it is no more effective and is more expensive than crystalloid solutions. Human albumin 20% solution is used in the management of hypoproteinaemic oedema in nephrotic syndrome (p. 395) and ascites in chronic liver disease (p. 864). It is hyperoncotic and expands plasma volume by more than the amount infused.

Blood components and their use are summarised in Box 23.17.

**Blood donation**

A safe supply of blood components depends on a well-organised system with regular donation by healthy individuals who have no excess risk of infections transmissible in blood (Fig. 23.14). Blood donations are obtained by either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis, the donor’s blood is drawn via a closed system into a machine that separates the components by centrifugation and collects the desired fraction into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B virus (HBV), hepatitis C virus (HCV), HIV and human T-cell lymphotropic virus (HTLV) nucleic acid and/or antibodies. Platelet concentrates may be tested for bacterial contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for Trypanosoma cruzi (Chagas’ disease; p. 279) is necessary in areas of South America and the USA where infection is prevalent. Tests for West Nile virus have been required in the USA since this agent became allogeneic transfusion may be avoided by following protocols that recommend the use of low haemoglobin thresholds for red cell transfusion, perioperative blood salvage and antifibrinolytic drugs.
Two hundred thousand transfusions are performed each year in the UK, with a prevalence of adverse effects. Components for use in specific patient groups are prepared from hepatitis E virus-negative donors in the UK, and plasma donated in the UK is not used at present for producing pooled plasma derivatives in view of concerns about transmission of variant Creutzfeldt–Jakob disease (vCJD; p. 1127).

### Acute effects of transfusion

Death directly attributable to transfusion is rare, at less than 0.3 per 100 000 transfusions. Relatively minor symptoms of transfusion reactions (fever, itch or urticaria) occur in up to 3% of transfusions, and usually in patients who have had repeated transfusions. Any symptoms or signs that arise during a transfusion must be taken seriously, as they may be the first warnings of a serious reaction. Figure 23.16 below outlines the symptoms and signs, management and investigation of acute reactions to blood components.

### Red cell incompatibility

Red blood cell membranes contain numerous cell surface molecules that are potentially antigenic (see Fig. 23.4). The ABO and Rhesus D antigens are the most important in routine transfusion and antenatal practice.

#### ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The ABO gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain, which has three common alleles: A, B and O. The O allele encodes an inactive enzyme, leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by
If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the recipient’s IgM anti-A, anti-B or anti-AB binds to the transfused red cells. This activates the full complement pathway (p. 66), creating pores in the red cell membrane and destroying the red cells. Individuals are tolerant to their own ABO antigens, but do not suppress B-cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 23.18). They are, therefore, capable of mounting a humoral immune response to these ‘foreign’ antigens.

**ABO-incompatible red cell transfusion**

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the recipient’s IgM anti-A, anti-B or anti-AB binds to the transfused red cells. This activates the full complement pathway (p. 66), creating pores in the red cell membrane and destroying...
the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin 1 (IL-1) and IL-8, and stimulate degranulation of mast cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension, which may, in turn, cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20–30% of ABO-incompatible transfusions cause some degree of morbidity, and 5–10% cause or contribute to a patient’s death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

The Rhesus D blood group and haemolytic disease of the newborn

About 15% of Caucasians are Rhesus-negative; that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 23.4). In other populations (e.g. in Chinese and Bengalis), only 1–5% are Rhesus-negative. RhD-negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD-positive red cells enter the circulation of an RhD-negative individual, IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via fetomaternal haemorrhage, or following transfusion. If a woman is so sensitised, during a subsequent pregnancy anti-RhD antibodies can cross the placenta; if the fetus is RhD-positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD-negative female who may subsequently become pregnant should never be transfused with RhD-positive blood.

In RhD-negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of Rhesus antibodies (Box 23.19). HDN can also be caused by other alloantibodies against red cell antigens, usually after previous pregnancies or transfusions. These antigens include Rhc, RhC, RHe, Rhe, and the Kell, Kidd and Duffy antigen systems. HDN can also occur if there is fetomaternal ABO incompatibility, most commonly seen in a group O mother with a group A fetus. The fetus is generally less severely affected by ABO incompatibility than by RhD, Rhc or Kell antigen mismatch, and the incompatibility is often picked up coincidentally after birth.

Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease (TA GVHD). The latter occurs when there is sharing of a human leucocyte antigen (HLA) haplotype between donor and recipient, which allows transfused lymphocytes to engraft, proliferate and recognise the recipient as foreign, resulting in acute GVHD (p. 937). Prevention is by gamma- or X-ray irradiation of blood components before their administration to prevent lymphocyte proliferation. Those at risk of TA GVHD, who must receive irradiated blood components, include patients with congenital T-cell immunodeficiencies or Hodgkin lymphoma, patients with aplastic anaemia receiving immunosuppressive therapy with antithymocyte globulin (ATG), recipients of haematopoietic stem cell transplants or of blood from a family member, neonates who have received an intrauterine transfusion, and patients taking T-lymphocyte-suppressing drugs, such as fludarabine and other purine analogues.

Transfusion-transmitted infection

Over the past 30 years, HBV, HIV-1 and HCV have been identified and effective tests introduced to detect and exclude infected donations. Where blood is from ‘safe’ donors and correctly tested, and effective tests introduced to detect and exclude infected donations. Where blood is from ‘safe’ donors and correctly tested, the current risk of a donated unit being infectious is very small. By 2013 in the UK, the estimated chance that a unit of blood from a ‘safe’ donor might transmit one of the viruses for which blood is tested was 1 in 6.6 million units for HIV-1, 1 in 51.5 million for HBV and 1 in 2.6 million for HCV. However, some patients who received transfusions before these tests were available suffered serious consequences from infection; this serves as a reminder to avoid non-essential transfusion, since it is impossible to exclude the emergence of new or currently unrecognised transfusion-transmissible infection. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

Variant CJD is a human prion disease linked to bovine spongiform encephalitis (BSE; p. 1127). The risk of a recipient acquiring the agent of vCJD from a transfusion is uncertain, but of 16 recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 1 other had postmortem immunohistological features of infection.

Bacterial contamination of a blood component – usually platelets – is extremely rare (1 proven case in the UK in 2015) but can result in severe bacteraemia/sepsis in the recipient.
Safe transfusion procedures

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative, and this should be documented in the case record. Some patients, e.g. Jehovah’s Witnesses, may refuse transfusion and require specialised management to survive profound anaemia following blood loss.

Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a ‘group and screen’ procedure or a ‘cross-match’. In the group and screen procedure, the red cells from the patient’s blood sample are tested to determine the ABO and RhD type, and the patient’s serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen can be selected. The patient’s sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cells with the patient’s serum. Full cross-matching takes about 45 minutes if no red cell antibodies are present, but may require hours if a patient has multiple antibodies.

Blood can be supplied by ‘electronic issue’, without the need for compatibility cross-matching, if the laboratory’s computer system shows that the patient’s ABO and RhD groups have been identified and confirmed on two separate occasions and their antibody screen is negative. This allows group-specific units to be issued quickly and safely, for elective and emergency transfusion.

Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Most incompatible transfusions result from failure to adhere to standard procedures for taking correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2015, there were 280 reports of transfusion of an incorrect blood component (11 per 100,000 units transfused). Every hospital where blood is transfused should have a written transfusion policy used by all staff who order, check or administer blood products (Fig. 23.15). Management of suspected transfusion reactions is shown in Figure 23.16.

Transfusion in major haemorrhage

The successful management of a patient with major haemorrhage requires frontline clinical staff to be trained to recognise significant blood loss early and to intervene before shock is established. Hospitals should have local major haemorrhage protocols and all clinical staff must be familiar with their content. Good team working and communication are essential to prevent poor clinical outcome, suboptimal or inappropriate transfusion practice and component wastage. Fresh frozen plasma (FFP) should be given as part of initial resuscitation in (at least) a 1:2 ratio with red cell concentrate (RCC) until coagulation results are available. If the patient is bleeding, a ratio of FFP to RCC of 1:1 should be given until laboratory results are available and use of cryoprecipitate should be considered. Once the bleeding is under control, further

Taking blood for pre-transfusion testing

- Positively identify the patient at the bedside
- Label the sample tube and complete the request form clearly and accurately after identifying the patient
- Do not write forms and labels in advance

Administering blood

- Positively identify the patient at the bedside
- Ensure that the identification of each blood pack matches the patient’s identification
- Check that the ABO and RhD groups of each pack are compatible with the patient’s
- Check each pack for evidence of damage
- If in doubt, do not use and return to the blood bank
- Complete the forms that document the transfusion of each pack

Record-keeping

- Record in the patient’s notes, the reason for transfusion, the product given, dose, any adverse effects and the clinical response

Observations

- Transfusions should only be given when the patient can be observed
- Blood pressure, pulse and temperature should be monitored before and 15 minutes after starting each pack
- In conscious patients, further observations are only needed if the patient has symptoms or signs of a reaction
- In unconscious patients, check pulse and temperature at intervals during transfusion
- Signs of abnormal bleeding during the transfusion could be due to disseminated intravascular coagulation resulting from an acute haemolytic reaction

Fig. 23.15 Bedside procedures for safe blood transfusion. The patient’s safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.
**Fig. 23.16** Investigation and management of acute transfusion reactions. *Use size-appropriate dose in children. (ARDS = acute respiratory distress syndrome; BP = blood pressure; CVP = central venous pressure; DIC = disseminated intravascular coagulation; FBC = full blood count; IV = intravenous)
FFP transfusion should be guided by laboratory results with transfusion triggers of PT and/or APTT above 1.5 times normal for a standard dose of FFP (15–20 mL/kg). Cryoprecipitate should be given if the fibrinogen level falls below 1.5 g/L. Platelets should be kept above 50×10⁹/L, and platelet transfusion should be guided by laboratory results with platelet count below 50×10⁹/L. Platelet transfusion triggers of PT and/or APTT above 1.5 times normal should be used in bleeding episodes. It is recommended that transfusion should be carried out at night only in unavoidable circumstances.

**Key points in transfusion medicine**

- A restrictive strategy for red cell transfusion (Hb < 70 g/L) is at least as effective as a liberal strategy (< 100 g/L).
- The majority of reports in haemovigilance schemes such as SHOT relate to errors in the process of transfusion.
- Although transfusion-transmitted infection is a major concern for patients receiving transfusion, it is rare.
- In patients with trauma or burns or those who have had surgery, there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions.
- It is recommended that transfusion should be carried out at night only in unavoidable circumstances.

(SHOT = Serious Hazards of Transfusion)

**Chemotherapy**

Chemotherapy refers to the use of drugs to treat cancer (Box 23.21; see also Fig. 33.2, p. 1317). Many haematological malignancies are sensitive to the effects of chemotherapy drugs and, as such, chemotherapy is the mainstay of treatment for most haematological cancers. There is a wide range of drugs available that work by damaging DNA or disrupting cellular metabolism, in such a way that natural apoptosis mechanisms, such as TP53, are activated and the cell dies. Despite cancer cells being more sensitive, chemotherapy is largely non-specific and kills some normal cells as well as cancer cells. This leads to common side-effects of treatment, such as transient bone marrow failure, mucositis and infertility. The supportive care of patients undergoing chemotherapy is critical in overcoming these side-effects. It is this supportive care, including blood product support, antibiotics, antifungal drugs, growth factors and antiemetics, that has allowed specialist haematology units to achieve the best possible results from intensive chemotherapy: for example, when treating acute leukaemia.

The basic principles of chemotherapy include combining several non-cross-reacting drugs in a regimen that kills a fixed proportion of cancer cells with a given dose. Several cycles of the combination are given to achieve gradual reduction of the tumour burden, to induce remission and, in some instances, to produce a cure (p. 1330).

In recent years, chemotherapy has been improved by the addition of treatments that are more targeted to the cancer cell, particularly monoclonal antibodies; for example, rituximab (anti-CD20) has been added to CHOP (cyclophosphamide, doxorubicin, vincristine, prednisolone) and other regimens, significantly improving the outcome in a range of CD20-positive B-cell lymphomas, including diffuse large B-cell lymphoma, follicular lymphoma and mantle cell lymphoma. Chemotherapy drugs can also be linked to a monoclonal antibody to allow targeting of the chemotherapy drug to the specific cancer cell. Examples of such antibody–drug conjugates (ADCs) include the linking of the intercalating antibiotic calicheamicin to anti-CD33 (gemtuzumab ozogamicin) to treat acute myeloid leukaemia, and to anti-CD22 (inotuzumab ozogamicin) to treat acute lymphoblastic leukaemia. Small molecules targeted at the mechanisms causing cancer are replacing chemotherapy in some disease situations, such as tyrosine kinase inhibitors in chronic myeloid leukaemia and inhibitors of B-cell signalling in relapsed chronic lymphocytic leukaemia and lymphomas. More details of specific chemotherapies are given later in the chapter.

**Haematopoietic stem cell transplantation**

Transplantation of haematopoietic stem cells (HSCT) has offered the only hope of ‘cure’ in a variety of haematological and non-haematological disorders (Box 23.22). As standard treatment improves, the indications for HSCT are being refined and extended, although its use remains most common in haematological malignancies. The type of HSCT is defined according to the donor and source of stem cells:

- In allogeneic HSCT, the stem cells come from a donor – either a related donor (usually an HLA-identical sibling) or a closely HLA-matched volunteer unrelated donor (VUD).
- In an autologous transplant, the stem cells are harvested from the patient and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from the bone marrow or from the blood.

**Examples of commonly used groups of cancer drugs in haematology**

- **Alkylating agents**
  - Cross-link double-stranded DNA by adding an alkyl group, e.g. cyclophosphamide, melphalan, chlorambucil

- ** Anthracyclines**
  - Intercalate between base pairs in the DNA molecule, e.g. daunorubicin, doxorubicin, idarubicin

- **Antimetabolites**
  - Inhibit DNA and RNA synthesis, e.g. cytosine arabinoside, fludarabine, methotrexate

- **Vinca alkaloids**
  - Cause disruption of tubulin, e.g. vincristine, vinblastine

- **Topoisomerase II inhibitors**
  - Prevent DNA repair, e.g. etoposide, daunorubicin, mitoxantrone

An example of a common combination regimen is CHOP, used in lymphoma: cyclophosphamide, hydroxydaunorubicin (doxorubicin), oncovin (vincristine) and prednisolone, given every 21 days for six cycles.

**Indications for allogeneic haematopoietic stem cell transplantation**

- Neoplastic disorders affecting stem cell compartments (e.g. leukaemias)
- Failure of haematopoiesis (e.g. aplastic anaemia)
- Major inherited defects in blood cell production (e.g. thalassaemia, immunodeficiency diseases)
- Inborn errors of metabolism with missing enzymes or cell lines
Healthy bone marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably ‘conditioned’. The conditioning treatment (chemotherapy with or without radiotherapy) is ‘myeloablative’ or, increasingly, ‘non-myeloablative’. Myeloablative conditioning destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient’s haematopoietic tissues. Reduced intensity conditioning (non-myeloablative) relies on intense immunosuppression to provide ‘immunological space’ for transplanted stem cells. The infused donor cells ‘home’ to the marrow, engraft and produce enough erythrocytes, granulocytes and platelets for the patient’s needs after about 3–4 weeks. During this period of aplasia, patients are at risk of infection and bleeding, and require intensive supportive care as described on page 957. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, particularly in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor’s immune system can recognise residual recipient malignant cells and destroy them. This immunological ‘graft-versus-disease’ effect is a powerful tool against many haematological tumours and can be boosted post-transplantation by the infusion of T cells taken from the donor: so-called donor lymphocyte infusion (DLI).

Considerable morbidity and mortality are associated with HSCT. The best results are obtained in patients with minimal residual disease, and in those under 20 years of age who have an HLA-identical sibling donor. Reduced-intensity conditioning has enabled treatment of older or less fit patients. In this form of transplantation, rather than using very intensive myeloablative conditioning, which causes morbidity from organ damage, relatively low doses of chemotherapy drugs, such as fludarabine and cyclophosphamide or busulfan, are used in combination with antibodies such as alemtuzumab (which targets CD52 on mature lymphoid cells) or anti-thymocyte globulin (ATG) to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the ‘graft-versus-disease’ effect, which may be boosted by the elective use of donor T-cell infusions post-transplant. Such transplants have produced long-term remissions in some patients with acute leukaemia and myelodysplastic syndromes aged 40–65 years, who would not previously have been considered for a myeloablative allograft.

**Complications**

These are outlined in Boxes 23.23 and 23.24. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications, such as infection and GVHD, and there remains a significant risk of the haematological malignancy relapsing. The long-term survival for patients undergoing allogeneic HSCT in acute leukaemia is around 50%.

**Graft-versus-host disease**

GVHD is caused by the cytotoxic activity of donor T lymphocytes that become sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppressant drugs, including methotrexate, ciclosporin, alemtuzumab or ATG. Severe presentations are very difficult to control and, despite high-dose glucocorticoids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with glucocorticoids and prolonged immunosuppression with, for example, ciclosporin. Chronic GVHD results in an increased infection risk. However, associated with chronic GVHD are the graft-versus-disease effect and a lower relapse rate of the underlying malignancy.

**Autologous HSCT**

This procedure can also be used in haematological malignancies. The patient’s own stem cells from blood or marrow are first harvested and frozen. After conditioning myeloablative therapy, the autologous stem cells are rein infused into the blood stream in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. Autologous HSCT may be used for disorders that do not primarily involve the haematopoietic tissues, or for patients in whom very good remissions have been achieved. The most common indications are lymphomas and myeloma. The preferred source of stem cells for autologous transplants is peripheral blood (PBSCT). These stem cells engraft more...
quickly, marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Thus autologous stem cell transplantation carries a lower procedure-related mortality rate than allogeneic HSCT at around 5%, but there is a higher rate of recurrence of malignancy because the anti-malignancy effect is solely dependent on the conditioning chemotherapy with no ‘graft-versus-disease’ effect.

**Anticoagulant and antithrombotic therapy**

There are numerous indications for anticoagulant and antithrombotic medications (Box 23.25). The guiding principles are outlined here but management in specific indications is discussed elsewhere in the book. Broadly speaking, antithrombotic medications are of greater efficacy in the prevention of arterial thrombosis and of less value in the prevention of venous thromboembolism (VTE). Thus, antithrombotic agents, such as aspirin, clopidogrel and, increasingly, ticagrelor, are the drugs of choice in acute coronary events (p. 498) and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in VTE (p. 975) and management of atrial fibrillation (p. 471).

In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and antiplatelet drugs is used (p. 491).

A wide range of anticoagulant and antithrombotic drugs is used in clinical practice. These drugs and their modes of action are given in Box 23.26. Newer agents allow predictable anticoagulation without the need for frequent monitoring and dose titration. Although warfarin remains the mainstay for oral anticoagulation, newer oral anticoagulants (dabigatran, rivaroxaban, edoxaban and apixaban), which can be given at fixed doses with predictable effects and no need for monitoring, have now been approved for the prevention of perioperative VTE, the treatment of established VTE and the prevention of cardioembolic stroke in patients with atrial fibrillation.

**Heparins**

Unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) act by binding via a specific pentasaccharide in the heparin molecule to antithrombin. Fondaparinux is a synthetic pentasaccharide, which also binds antithrombin and has similar properties to LMWH. These agents enhance the natural anticoagulant activity of antithrombin (see Fig. 23.6E), increased cleavage of activated proteases, particularly factor Xa and thrombin (IIa), accounts for the anticoagulant effect. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH but have several advantages:

- LMWHs are nearly 100% bioavailable and so produce reliable dose-dependent anticoagulation.
- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients with very low body weight).

</table>
• While rates of bleeding are similar between products, LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or twice-daily subcutaneous administration required for UFH.

• While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.

UFH is, however, more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice (Box 23.27).

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 23.25. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous, except when rapid reversibility is required. UFH is useful in patients with a high risk of bleeding, e.g. those who have peptic ulceration or who may require urgent surgery. It is also favoured in the treatment of life-threatening thromboembolism, e.g. major pulmonary embolism with significant hypoxaemia, hypotension and right-sided heart strain. In this situation, UFH is started with a loading intravenous dose of 80 U/kg, followed by a continuous infusion of 18 U/kg/hr initially. The level of anticoagulation should be assessed by the APTT after 6 hours and, if satisfactory, twice daily thereafter. It is usual to aim for a patient APTT that is 1.5–2.5 times the control time of the test. Monitoring of UFH treatment by APTT is not without difficulties and other assays, such as the specific anti-Xa assay, may provide more accurate guidance.

Heparin-induced thrombocytopenia
Heparin-induced thrombocytopenia (HIT) is a rare complication of heparin therapy, caused by induction of anti-heparin/PF4 antibodies that bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with a paradoxical thrombocytopoenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin.

Clinical features
Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of more than 30% from baseline. The count may still be in the reference range. The patient may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms, such as shivering, following heparin injections. Patients who have received heparin in the preceding 100 days and who have preformed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

Investigations
The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the thrombocytopenia
- the timing of the fall in platelet count
- the presence of new thrombosis
- the likelihood of another cause for the thrombocytopenia.

Individuals at low risk need no further test. Those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using an anti-PF4 enzyme-linked immunosorbent assay (ELISA).

Management
Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant that does not cross-react with the antibody should be substituted. Argatroban (a direct thrombin inhibitor) and danaparoid (a heparin analogue) are licensed for use in the UK. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poorer prognosis.

Cumarins
Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K-dependent post-translational carboxylation of factors II (prothrombin), VII, IX and X in the liver (see Fig. 23.6D). This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (p. 922). Recommended target INR values for specific indications are given in Box 23.25.

Warfarin anticoagulation typically takes more than 3–5 days to become established, even using loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regime in this situation is to give 10 mg warfarin on the first and second days, with 5 mg on the third day; subsequent doses are titrated against the INR. Patients without an urgent need for anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supratherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication, and while treatment of deep vein thrombosis (DVT) or preparation for cardioversion may require a limited duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- a narrow therapeutic window
- metabolism that is affected by many factors
- numerous drug interactions.
Drug interactions are common through protein binding and metabolism by the cytochrome P450 system. Inter-individual differences in warfarin doses required to achieve a therapeutic INR are mostly accounted for by naturally occurring polymorphisms in the CYP2C9 and the VKORC1 genes (which predict the metabolism and function of warfarin, respectively) and dietary intake of vitamin K.

Major bleeding is the most common serious side-effect of warfarin and occurs in 1–2% of patients each year. Fatal haemorrhage, which is most commonly intracranial, occurs in about 0.25% per annum. There are scoring systems that predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box 23.28). There are also some specific contraindications to anticoagulation (Box 23.28). Management of warfarin includes strategies for over-anticoagulation and for bleeding:

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or intravenously (1–2.5 mg), especially if the INR is greater than 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K IV. Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly IV, combined with coagulation factor replacement (see Box 23.27). This should optimally be a prothrombin complex concentrate (30–50 U/kg) that contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

### Direct oral anticoagulants

The direct oral anticoagulants (DOACs) offer an alternative to coumarins in the management of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation. The DOACs are direct specific inhibitors of key proteases in the common pathway. Dabigatran inhibits thrombin while rivaroxaban, apixaban and edoxaban inhibit Xa. The key features of these drugs include the fact that they are efficacious in fixed oral doses, have a short half-life of around 10 hours, achieve peak plasma levels 2–4 hours after oral intake, have very few drug interactions and are all moderately dependent on renal function for their excretion. An initial perceived drawback was the lack of specific reversal agents for these drugs but idarucizumab is a monoclonal antibody now available for the reversal of dabigatran, and andexanet alfa, a site-inactivated Xa molecule, is close to licensing for the reversal of apixaban and rivaroxaban (see Box 23.27).

DOACs are now licensed for the prevention of VTE following high-risk orthopaedic surgery (except edoxaban), the acute management and prevention of recurrence of VTE, and the prevention of stroke and systemic embolism in patients with atrial fibrillation with risk factors. The general perception at present is that in these indications they are at least as efficacious as dose-adjusted coumarin and probably associated with less clinically significant bleeding.

### Anaemias

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs 23.10 and 23.11).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 23.17). While in the marrow compartment, red cell precursors undergo cell division, driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when finally released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassaemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease/anaemia of inflammation.

In megaloblastic anaemia, the biochemical consequence of vitamin B12 or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow, such as myelodysplasia. In these states, cells haemoglobinise normally but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer that will freely exchange with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised – e.g. in haemolysis – this may also increase the MCV.

### Iron deficiency anaemia

This occurs when iron losses or physiological requirements exceed absorption.

### Blood loss

The most common explanation in men and post-menopausal women is gastrointestinal blood loss (p. 780). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angiodysplastic lesions. Worldwide, hookworm and schistosomiasis are the most common causes of gut blood loss (pp. 288 and 294). Gastrointestinal blood loss may be exacerbated...
by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries, one-third of pre-menopausal women have low iron stores but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

Malabsorption

A dietary assessment should be made in all patients to ascertain their iron intake (p. 716). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 23.18). Achlorhydria in the elderly or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 805).

Physiological demands

At times of rapid growth, such as infancy and puberty, iron requirements increase and may outstrip absorption. In pregnancy, iron is diverted to the fetus, the placenta and the increased maternal red cell mass, and is lost with bleeding at parturition (Box 23.29).

Investigations

Confirmation of iron deficiency

Serum ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 23.30). It is a very specific test; a subnormal level is due to iron deficiency or, very rarely, hypothyroidism or vitamin C deficiency. Ferritin levels can be raised in liver disease and in the acute phase response; in these conditions, a ferritin level of up to 100 μg/L may still be compatible with low bone marrow iron stores.
Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, the acute phase response and nephrotic syndrome, but raised by pregnancy and the oral contraceptive pill. A transferrin saturation (i.e. iron/TIBC × 100) of less than 16% is consistent with iron deficiency but is less specific than a ferritin measurement.

All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. At times of poor iron stores, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can now be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease, when a raised level indicates iron deficiency. In difficult cases, it may still be necessary to examine a bone marrow aspirate for iron stores.

Investigation of the cause

This will depend on the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or radiological studies. Serum anti-transglutaminase antibodies and possibly a duodenal biopsy are indicated (p. 806) to detect coeliac disease. Current guidelines suggest exclusion of coeliac disease by antibody testing at an early stage of investigation. In the tropics, stool and urine should be examined for parasites (p. 233).
Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not necessary and oral iron replacement is appropriate. Ferrous sulphate 200 mg 3 times daily (195 mg of elemental iron per day) is adequate and should be continued for 3–6 months to replete iron stores. Many patients suffer gastrointestinal side-effects with ferrous sulphate, including dyspepsia and altered bowel habit. When this occurs, reduction in dose to 200 mg twice daily or a switch to ferrous gluconate 300 mg twice daily (70 mg of elemental iron per day) or another alternative oral preparation should be tried. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine, where it cannot be absorbed.

The haemoglobin should rise by around 10 g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-adherence, continued blood loss, malabsorption or an incorrect diagnosis. Patients with malabsorption, chronic gut disease or inability to tolerate any oral preparation may need parenteral iron therapy. Previously, iron dextran or iron sucrose was used, but new preparations of iron isomaltose and iron carboxymaltose have fewer allergic effects and are preferred. Doses required can be calculated based on the patient’s starting haemoglobin and body weight. Observation for anaphylaxis following an initial test dose is recommended.

Anaemia of chronic disease

Anaemia of chronic disease (ACD), also known as anaemia of inflammation (AI), is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with haemoglobin in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low but iron stores are normal or increased, as indicated by the ferritin or stainable marrow iron.

Pathogenesis

It has recently become clear that the key regulatory protein that accounts for the findings characteristic of ACD/AI is hepcidin, which is produced by the liver (see Fig. 23.18). Hepcidin production is induced by pro-inflammatory cytokines, especially IL-6. Hepcidin binds to ferroportin on the membrane of iron-exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood. The iron remains trapped inside the cells in the form of ferritin, levels of which are therefore normal or high in the face of significant anaemia. Inhibition or blockade of hepcidin is a potential target for treatment of this form of anaemia.

Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 23.30 summarises the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A positive response occurs in true iron deficiency but not in ACD. Measures that reduce the severity of the underlying disorder generally help to improve the ACD. Trials of higher-dose intravenous iron are under way to try to bypass the hepcidin-induced blockade.

Megaloblastic anaemia

This results from a deficiency of vitamin B₁₂ or folic acid, or from disturbances in folic acid metabolism. Folate is an important substrate of, and vitamin B₁₂ a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B₁₂ or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The end result is cells with arrested nuclear maturation but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early nucleated red cell precursors, and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis characteristic of other forms of haemolysis (p. 945). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of “giant” metamyelocytes with a large ‘sausage-shaped’ nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, a pancytopenia may be present in the peripheral blood.

Vitamin B₁₂ deficiency, but not folate deficiency, is associated with neurological disease in up to 40% of cases, although advanced neurological disease due to B₁₂ deficiency is now uncommon in the developed world. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesias and ataxia of gait. The clinical and diagnostic features of megaloblastic anaemia are summarised in Boxes 23.31 and 23.32, and the neurological features of B₁₂ deficiency in Box 23.33.

Vitamin B₁₂ absorption

The average daily diet contains 5–30 μg of vitamin B₁₂, mainly in meat, fish, eggs and milk – well in excess of the 1 μg daily
Not add much in most clinical situations. Levels of cobalamins fall in normal pregnancy. Reference ranges vary between laboratories but levels below 150 ng/L are common and, in the last trimester, 5–10% of women have levels below 100 ng/L. Spuriously low B₁₂ values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B₁₂ assays.

**Causes of vitamin B₁₂ deficiency**

**Dietary deficiency**

This occurs only in strict vegans but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B₁₂ levels but are not tissue vitamin B₁₂-deficient.

**Gastric pathology**

Release of vitamin B₁₂ from food requires normal gastric acid and enzyme secretion, and this is impaired by hypochlorhydria in elderly patients or following gastric surgery. Total gastrectomy invariably results in vitamin B₁₂ deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin B₁₂ injections. After partial gastrectomy, vitamin B₁₂ deficiency only develops in 10–20% of patients by 5 years; an annual injection of vitamin B₁₂ should prevent deficiency in this group.

**Pernicious anaemia**

This is an organ-specific autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin B₁₂ is absorbed. Pernicious anaemia has an incidence of 25/100 000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto’s thyroiditis, Graves’ disease, vitiligo or Addison’s disease; Ch. 18) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of B₁₂ deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely but a positive result is not diagnostic. The Schilling test, involving measurement of absorption of radio-labelled B₁₂ after oral administration before and after replacement of intrinsic factor, has fallen out of favour with the availability of autoantibody tests, greater caution in the use of radioactive tracers, and limited availability of intrinsic factor.

**Small bowel pathology**

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin B₁₂ from R protein to intrinsic factor. This usually results in slightly low vitamin B₁₂ values but no tissue evidence of vitamin B₁₂ deficiency.

Motility disorders or hypogammaglobulinaemia can result in bacterial overgrowth, and the ensuing competition for free vitamin B₁₂ can lead to deficiency. This is corrected to some extent by appropriate antibiotics.

A small number of people heavily infected with the fish tapeworm (p. 297) develop vitamin B₁₂ deficiency.

Inflammatory disease of the terminal ileum, such as Crohn’s disease, may impair the absorption of vitamin B₁₂–intrinsic factor complex, as may surgery on that part of the bowel.

requirement. In the stomach, gastric enzymes release vitamin B₁₂ from food and at gastric pH it binds to a carrier protein termed R protein. The gastric parietal cells produce intrinsic factor, a vitamin B₁₂-binding protein that optimally binds vitamin B₁₂ at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B₁₂ released from the diet switches from the R protein to intrinsic factor. Bile also contains vitamin B₁₂ that is available for reabsorption in the intestine. The vitamin B₁₂–intrinsic factor complex binds to specific receptors in the terminal ileum, and vitamin B₁₂ is actively transported by the enterocytes to plasma, where it binds to transcobalamin II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The liver stores enough vitamin B₁₂ for 3 years and this, together with the enterohepatic circulation, means that vitamin B₁₂ deficiency takes years to become manifest, even if all dietary intake is stopped or severe B₁₂ malabsorption supervenes.

Blood levels of vitamin B₁₂ (cobalamin) provide a reasonable indication of tissue stores, are usually diagnostic of deficiency and remain the first-line tests for most investigations. Additional tests have been evaluated, including measurement of methylmalonic acid, holotranscobalamin and plasma homocysteine levels, but do not add much in most clinical situations. Levels of cobalamins fall in normal pregnancy. Reference ranges vary between laboratories but levels below 150 ng/L are common and, in the last trimester, 5–10% of women have levels below 100 ng/L. Spuriously low B₁₂ values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B₁₂ assays.
Folate

**Folate absorption**

Folates are produced by plants and bacteria; hence dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50 μg but excess cooking destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is an enterohepatic circulation. Total body stores of folate are small and deficiency can occur in a matter of weeks.

**Folate deficiency**

The causes and diagnostic features of folate deficiency are shown in Boxes 23.34 and 23.35. The edentulous elderly or psychiatric patient is particularly susceptible to dietary deficiency and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis worldwide and is more likely in the context of twin pregnancies, multiparity and hyperemesis gravidarum. Serum folate measurement is very sensitive to dietary intake; a single folate-rich meal can normalise it in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant therapy can reduce it in the absence of megaloblastosis. For this reason, red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

**Management of megaloblastic anaemia**

If a patient with a severe megaloblastic anaemia is very ill and treatment must be started before vitamin B₁₂ and red cell folate results are available, that treatment should always include both folic acid and vitamin B₁₂. The use of folic acid alone in the presence of vitamin B₁₂ deficiency may result in worsening of neurological features.

Rarely, if severe angina or heart failure is present, transfusion can be used in megaloblastic anaemia. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis, and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 U of red cells with diuretic cover may be given.

**Vitamin B₁₂ deficiency**

Vitamin B₁₂ deficiency is treated with hydroxocobalamin. In cases of uncomplicated deficiency, 1000 μg IM for 6 doses 2 or 3 days apart, followed by maintenance therapy of 1000 μg every 3 months for life, is recommended. In the presence of neurological involvement, a dose of 1000 μg on alternate days until there is no further improvement, followed by maintenance as above, is recommended. The reticulocyte count will peak by the 5th–10th day after starting replacement therapy. The haemoglobin will rise by 10 g/L every week until normalised. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. A sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

**Folate deficiency**

Oral folic acid (5 mg daily for 3 weeks) will treat acute deficiency and 5 mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at risk, and reduces the risk of fetal neural tube defects (p. 712). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. haemolytic anaemias). There is some evidence that supraphysiological supplementation (400 μg/day) can reduce the risk of coronary and cerebrovascular disease by lowering plasma homocysteine levels. This has led the US Food and Drug Administration to introduce fortification of bread, flour and rice with folic acid.

---

**Haemolytic anaemia**

Haemolysis indicates that there is shortening of the normal red cell lifespan of 120 days. There are many causes, as shown in Figure 23.19. To compensate, the bone marrow may increase its output of red cells six- to eightfold by increasing the proportion of red cells produced, expanding the volume of active marrow, and releasing reticulocytes prematurely. Anaemia occurs only if the rate of destruction exceeds this increased production rate.

There are some general features of haemolysis and other specific features that help to identify the reason for haemolysis. Results of investigations that establish the presence of haemolysis are shown in Box 23.36. Red cell destruction overloads pathways for haemoglobin breakdown in the liver (p. 850), causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobinogen from the gut results in an increase in urinary urobilinogen (pp. 860 and 915). Red cell destruction releases LDH into the serum. The bone
The red cells may give an indication of the likely cause of the haemolysis:

- Spherocytes are small, dark red cells that suggest autoimmune haemolysis or hereditary spherocytosis.
- Sickle cells suggest sickle-cell disease.
- Red cell fragments indicate microangiopathic haemolysis.
- Bite cells (normal-sized red cells that look as if they have been partially eaten) suggest oxidative haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 23.19).

Extravascular haemolysis

Physiological red cell destruction occurs in the reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the marrow compensation results in a reticulocytosis, and sometimes nucleated red cell precursors appear in the blood. Increased proliferation of the bone marrow can result in a thrombocytosis, neutrophilia and, if marked, immature granulocytes in the blood, producing a leucoerythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis:

- Spherocytes are small, dark red cells that suggest autoimmune haemolysis or hereditary spherocytosis.
- Sickle cells suggest sickle-cell disease.
- Red cell fragments indicate microangiopathic haemolysis.
- Bite cells (normal-sized red cells that look as if they have been partially eaten) suggest oxidative haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 23.19).

Extravascular haemolysis

Physiological red cell destruction occurs in the reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the

---

**Fig. 23.19 Causes and classification of haemolysis.**

**[A]** Inherited causes. **B** Acquired causes. (CLL = chronic lymphocytic leukaemia; \(\text{DIC} = \) disseminated intravascular coagulation; \(\text{EBV} = \) Epstein–Barr virus; \(\text{G6PD} = \) glucose-6-phosphate dehydrogenase; \(\text{HUS} = \) haemolytic uraemic syndrome; \(\text{PK} = \) pyruvate kinase; \(\text{RA} = \) rheumatoid arthritis; \(\text{SLE} = \) systemic lupus erythematosus; \(\text{TTP} = \) thrombotic thrombocytopenic purpura)
plasma. In most haemolytic states, haemolysis is predominantly extravascular.

To confirm the haemolysis, patients’ red cells can be labelled with $^{51}$chromium. When re-injected, they can be used to determine red cell survival; when combined with body surface radioactivity counting, this test may indicate whether the liver or the spleen is the main source of red cell destruction. However, it is seldom performed in clinical practice.

**Intravascular haemolysis**

Less commonly, red cell lysis occurs within the blood stream due to membrane damage by complement (ABO transfusion reactions, paroxysmal nocturnal haemoglobinuria), infections (malaria, Clostridium perfringens), mechanical trauma (heart valves, DIC) or oxidative damage (e.g. enzymopathies such as glucose-6-phosphate dehydrogenase deficiency, which may be triggered by drugs such as dapsone and maloprim). When intravascular red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an $\alpha_2$-globulin produced by the liver, which binds free haemoglobin, resulting in a fall in its levels during active haemolysis. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin, which binds to albumin, in turn forming methaemalbumin, which can be detected spectrophotometrically in Schumm’s test. Methaemoglobin is degraded and any free haem is bound to a second binding protein called haemopexin. If all the protective mechanisms are saturated, free haemoglobin may appear in the urine (haemoglobinuria). When fulminant, this gives rise to black urine, as in severe *falciparum* malaria infection (p. 274). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give rise to haemosiderinuria, which is always indicative of intravascular haemolysis (Box 23.36).

**Causes of haemolytic anaemia**

These can be classified as inherited or acquired (Fig. 23.19).

- **Inherited** red cell abnormalities resulting in chronic haemolytic anaemia may arise from pathologies of the red cell membrane (hereditary spherocytosis or elliptocytosis), haemoglobin (haemoglobinopathies), or protective enzymes that prevent cellular oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD).
- **Acquired** causes include auto- and alloantibody-mediated destruction of red blood cells and other mechanical, toxic and infective causes.

**Red cell membrane defects**

The structure of the red cell membrane is shown in Figure 23.4. The basic structure is a cytoskeleton ‘stapled’ on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity; the red cell diameter is 8 $\mu$m but the narrowest capillaries in the circulation are in the spleen, measuring just 2 $\mu$m in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell shape (see Box 23.2) and reduced red cell survival due to extravascular haemolysis.

**Hereditary spherocytosis**

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1:5000 in developed countries but this may be an under-estimate, since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 23.4). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, a reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or co-inheritance of a second defect involving a different protein. These cases tend to present earlier in life with symptomatic, sometimes transfusion-dependent anaemia.

The clinical course may be complicated by crises:

- **A haemolytic crisis** occurs when the severity of haemolysis increases; this is rare, and usually associated with infection.
- **A megaloblastic crisis** follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- **An aplastic crisis** occurs in association with parvovirus (erythrovirus) infection (p. 237). Parvovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

**Investigations**

The patient and other family members should be screened for features of compensated haemolysis (see Box 23.36). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes but the direct Coombs test (Fig. 23.20) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions but is limited by lack of sensitivity and specificity. More specific flow cytometric tests, detecting binding of eosin-5-maleimide to red cells, are recommended in borderline cases.

**Management**

Folic acid prophylaxis, 5 mg daily, should be given for life. In severe cases, consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications for splenectomy include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed where possible until after 6 years of age in view of the risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 23.37.

Acute, severe haemolytic crises require transfusion support, but blood must be cross-matched carefully and transfused slowly as haemolytic transfusion reactions may occur (p. 935).

**Hereditary elliptocytosis**

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional
A characteristic variant of hereditary elliptocytosis occurs in South-east Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The blood film is often very abnormal and immediate differential diagnosis is broad.

Red cell enzymopathies

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume while protecting itself from the oxidative stress presented by oxygen carriage. ATP is generated by glycolysis, while the hexose monophosphate shunt produces nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends on the importance of the steps affected and the presence of alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis precipitated by episodic oxidative stress, while those in the glycolysis pathway result in shortened red cell survival and chronic haemolysis.

Glucose-6-phosphate dehydrogenase deficiency

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzymopathy, affecting 10% of the world’s population, with a geographical distribution that parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits that are encoded by a gene on the X chromosome. The deficiency therefore affects males and rare
enzyme levels as low as 1%. In Caucasian and East Asian populations is more severe, with have enzyme levels of about 15% of normal. The deficiency of males and 4% of females (homozygotes) are affected and support may be life-saving.

The consumption of fava beans is the classically described precipitant of haemolysis in patients with G6PD deficiency. Acute transfusion support may be necessary during periods of haemolysis.

Non-spherocytic intravascular haemolysis during an attack
The blood film will show:
- Bite cells (red cells with a ‘bite’ of membrane missing)
- Blister cells (red cells with surface blistering of the membrane)
- Irregularly shaped small cells
- Polychromasia reflecting the reticulocytosis
- Denatured haemoglobin visible as Heinz bodies within the red cell cytoplasm with a supravital stain such as methyl violet

G6PD level
- Can be indirectly assessed by screening methods that usually depend on the decreased ability to reduce dyes
- Direct assessment of G6PD is made in those with low screening values
- Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result

Pyrimidine 5’ nucleotidase deficiency
The pyrimidine 5’ nucleotidase enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see Box 23.2), associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

Autoimmune haemolytic anaemia
This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or IgM, or more rarely IgE or IgA. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular (in the reticulo-endothelial system). Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:
- Warm antibodies bind best at 37°C and account for 80% of cases. The majority are IgG and often react against Rhesus antigens.
- Cold antibodies bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. To be clinically relevant, they must act within the range of normal body temperatures. They account for the other 20% of cases.

Warm autoimmune haemolysis
The incidence of warm autoimmune haemolysis is approximately 1/100,000 population per annum; it occurs at all ages but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions (see Fig. 23.19B).

Management
There is evidence of haemolysis, spherocytes and polychromasia on the blood film. The diagnosis is confirmed by the direct Coombs or antiglobulin test (see Fig. 23.20). The patient’s red cells are mixed with Coombs reagent, which contains antibodies against human IgG/IgM/complement. If the red cells have been coated by antibody in vivo, the Coombs reagent will induce their agglutination and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is for Rhesus antigens and most often anti-e; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies. Around 10% of all warm autoimmune haemolytic anaemias are Coombs test-negative.

Pyridoxine-dependent anaemia
This is a rare autosomal recessive disorder which presents in infancy. The red cell defect is pyridoxine-dependent: red cells are normal in the absence of pyridoxine (vitamin B6), but haemolytic anaemia develops on pyridoxine withdrawal.

Management
If the haemolysis is secondary to an underlying cause, this must be treated and any implicated drugs stopped.
It is usual to treat patients initially with prednisolone (1 mg/kg orally). A response is seen in 70–80% of cases but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticulocyte counts. Once the haemoglobin has normalised and the reticulocytosis resolved, the glucocorticoid dose can be reduced slowly over several weeks. Glucocorticoids probably work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production.

Transfusion support may be required for life-threatening problems, such as the development of heart failure or rapid unabated falls in haemoglobin. The least incompatible blood should be used but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to glucocorticoids or can only be stabilised by large doses, then second-line therapies should be considered. These include immunomodulation/suppression and splenectomy. Currently, there are fewer splenectomies than previously and the second-line drug of choice in current UK guidance is the anti-CD20 monoclonal antibody rituximab. Splenectomy is associated with a good response in 50–60% of cases. The operation can be performed laparoscopically with reduced morbidity. If splenectomy is not appropriate, alternative immunosuppressive therapy with azathioprine, ciclosporin, mycophenolate or cyclophosphamide may be considered. There are concerns about all modes of second-line therapy, as long-term immunosuppression carries a risk of malignancy, while splenectomy is associated with an excess of severe infection due to the capausible organisms pneumococcus and meningococcus (see Box 23.40).

Cold agglutinin disease

This is mediated by antibodies, usually IgM, which bind to the red cells at low temperatures and cause them to agglutinate. It may cause intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.

Chronic cold agglutinin disease

This typically affects elderly patients and may be associated with an underlying low-grade B-cell lymphoma. It causes a low-grade intravascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (so-called acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder, exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously high because the automated analysers detect red cell aggregates as single cells. Monoclonal IgM usually has anti-i or, less often, anti-i specificity. Treatment is primarily by transfusion support but may also be directed at any underlying lymphoma. Patients must keep extremities warm, especially in winter. Some patients respond to glucocorticoid therapy and rituximab. Two considerations for patients requiring blood transfusion is that the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood administered via a blood-warmer. All patients should receive folic acid supplementation.

Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneumoniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children, in association with viral or bacterial infection. An IgG antibody binds to red cells in the peripheral circulation but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath–Landsteiner antibody and has specificity against the P antigen on the red cells.

### Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is caused by antibodies against non-self red cells. It has two main causes, occurring after:

- unmatched blood transfusion (p. 935)
- maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, p. 933).

### Non-immune haemolytic anaemia

#### Endothelial damage

Disruption of red cell membrane may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- **Mechanical heart valves.** High flow through incompetent valves or perioprothetic leaks through the suture ring holding a valve in place result in shear stress damage.
- **March haemoglobinuria.** Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- **Thermal injury.** Severe burns cause thermal damage to red cells, characterised by fragmentation and the presence of microspherocytes in the blood.
- **Microangiopathic haemolytic anaemia.** Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (p. 408), thrombotic thrombocytopenic purpura (p. 979) and disseminated intravascular coagulation (p. 978).

#### Infection

*Plasmodium falciparum* malaria (p. 274) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever because of the associated haemoglobinuria. *Clostridium perfringens* sepsis (p. 227), usually in the context of ascending cholangitis or necrotising fasciitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecithinase that destroys the red cell membrane.

#### Chemicals or drugs

Dapsone and sulphasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrates and nitrobenzene derivatives may all cause haemolysis.

#### Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired, non-malignant clonal expansion of haematopoietic stem cells deficient in glycosylphosphatidylinositol (GPI) anchor protein. GPI anchors several key molecules to cells and its absence results in clinical outcomes that reflect this, causing intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. This happens because key defence mechanisms that protect cells from complement-mediated lysis (CD55 and CD59) are GPI-anchored to red cells under normal circumstances. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine, which...
Haemoglobinopathies

These diseases are caused by mutations affecting the genes encoding the globin chains of the haemoglobin molecule. Normal haemoglobin is composed of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, including in the fetus, so severe mutations may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (HbF-αα/γγ) has two gamma chains, while the predominant adult haemoglobin (HbA-αα/ββ) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A2 (HbA2-αα/δδ, usually less than 2%) is made from birth.

The geographical distribution of the common haemoglobinopathies is shown in Figure 23.21. The haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

Qualitative abnormalities – abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobins), there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but the more recently described ones are known by names that usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell anaemia. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

Quantitative abnormalities – thalassaemias

In quantitative abnormalities (the thalassaemias), there are mutations causing a reduced rate of production of one or other of the globin chains, altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, while in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival due to haemolysis.

Sickle-cell anaemia

Sickle-cell disease results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait (p. 48). Homozygotes only produce abnormal beta chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disease. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in sickle-cell trait; although this was previously thought of as asymptomatic, it may be associated with an increased risk of sudden and cardiovascular death.

Epidemiology

The heterozygote frequency is over 20% in tropical Africa (see Fig. 23.21). In black American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the lethal effects of falciparum malaria in early childhood; the high prevalence in equatorial Africa can be explained by the survival advantage it confers in areas where falciparum malaria is endemic. However, homozygous patients with sickle-cell anaemia do not have correspondingly greater resistance to falciparum malaria.

Pathogenesis

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as ‘tactoids’. These distort the red cell membrane and has a characteristic red–brown colour. The disease is associated with an increased risk of venous and arterial thrombosis in unusual sites, such as the liver or abdomen. PNH clones are also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (pp. 960 and 969). Management is supportive with transfusion and folate supplements and prophylaxis or treatment of thrombosis. Standard care now includes the anti-complement C5 monoclonal antibody eculizumab. This has been shown to be effective in reducing haemolysis, transfusion requirements and thrombotic risk. Eculizumab carries a risk of infection, particularly for Neisseria meningitidis, and all treated patients must be vaccinated against this organism.
produce characteristic sickle-shaped cells (Fig. 23.22). The polymerisation is reversible when re-oxygenation occurs. The distortion of the red cell membrane, however, may become permanent and the red cell ‘irreversibly sickled’. The greater the concentration of sickle-cell haemoglobin in the individual cell, the more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus the abnormal haemoglobin C variant participates in polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

**Clinical features**

Sickling is precipitated by hypoxia, acidosis, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the microcirculation. This results in a number of acute syndromes, termed ‘crises’, and chronic organ damage (Fig. 23.22):

- **Painful vaso-occlusive crisis.** Plugging of small vessels in the bone produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebrae in adults. Patients usually have a systemic response with tachycardia, sweating and a fever. This is the most common form of crisis.

- **Stroke.** The single most devastating consequence of sickle-cell disease is stroke. Stroke or silent stroke occurs in 10–15% of children with sickle-cell disease. Children at risk of stroke can be identified by screening with transcranial Doppler ultrasound, with fast flow associated with increased stroke risk. These children may be offered strategies such as transfusion or treatment with hydroxycarbamide to reduce the risk of stroke.

- **Sickle chest syndrome.** This may follow a vaso-occlusive crisis and is the most common cause of death in adult sickle-cell disease. Bone marrow infarction results in fat emboli to the lungs, which cause further sickling and infarction, leading to ventilatory failure if not treated.

- **Sequestration crisis.** Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children, the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction and adults may have no functional spleen. In adults, the liver may undergo sequestration with severe pain due to capsular stretching. Priapism is a complication seen in affected men.

- **Aplastic crisis.** Infection of adult sicklers with human parvovirus B19 (erythrovirus) may result in a severe but
Haemoglobinopathies - Page 953

23.39 Sickle-cell disease in pregnancy

- Pre-conceptual counselling: advice on the effect of sickle-cell disease on pregnancy, and vice versa, should be offered.
- Vaccination status: should be updated before conception.
- Testing of partner: testing for haemoglobinopathy status is advised.
- Folic acid: should be taken in high doses (5 mg daily) prior to and throughout pregnancy.
- Hydroxyurea: should be discontinued 3 months prior to conception.
- Angiotensin-converting enzyme (ACE) inhibitors: should be discontinued prior to conception.
- Pulmonary hypertension: should be excluded prior to conception.
- Placental failure: women with sickle-cell disease have increased rates, resulting in pre-eclampsia and intrauterine growth retardation.
- Aspirin 75 mg: should be given throughout pregnancy.
- Thromboprophylaxis after delivery: all women with sickle-cell disease should receive thromboprophylaxis with low-molecular-weight heparin for at least 10 days post vaginal delivery and for 6 weeks post caesarean section. Antenatal thromboprophylaxis should be considered for women with additional risk factors for venous thromboembolism (see Box 23.65).
- Transfusion: extended cross-matched blood for Rhesus and Kell status should be provided. Blood should be cytomegalovirus-negative.

Investigations

Patients with sickle-cell disease have a compensated anaemia, which may cause heart failure. Unlike in all other sickle crises, the reticulocyte count is low.

- Pregnancy. Pregnancy in sickle-cell disease requires planning and multidisciplinary management. Women with sickle-cell disease have increased pregnancy-related morbidity, which includes painful crisis, placental failure and thrombosis (Box 23.39).

Management

All patients with sickle-cell disease should receive prophyaxis with daily folic acid, and appropriate management of the hypoplastic state that is uniformly found in these patients from an early age (see Box 23.37). Seasonal vaccination against influenza is also advised in these patients.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with fully genotyped blood wherever possible. Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications, such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesected and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disease and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxyurea has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises.

Relatively few allogeneic stem cell transplants from HLA-matched siblings have been performed but this procedure appears to be potentially curative (p. 937).

Prognosis

In Africa, few children with sickle-cell anaemia survive to adult life without medical attention. Even with standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

Other abnormal haemoglobins

Another beta-chain haemoglobinopathy, haemoglobin C (HbC) disease, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one HbS gene and one HbC gene from their parents have haemoglobin SC disease, which behaves like a mild form of sickle-cell disease. SC disease is associated with a reduced frequency of crises but is not uncommonly associated with complications in pregnancy and retinopathy.

Thalassaemias

Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesize a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point mutations causing no (β0) or reduced (β+) beta chain production.

Beta-thalassaemia

Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild microcytic anaemia and little or no clinical disability, which may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or, at best, produce very little; after the first 4–6 months of life, they develop profound transfusion-dependent hypochromic anaemia. The diagnostic features are summarised in Box 23.40. Intermediate grades of severity occur.

Management and prevention

See Box 23.41. Cure is now a possibility for selected children, with allogeneic HSCT (p. 937).

It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA
23.40 Diagnostic features of beta-thalassaemia

Beta-thalassaemia major (homozygotes)
- Profound hypochromic anaemia
- Evidence of severe red cell dysplasia
- Erythroid hyperplasia
- Absence or gross reduction of the amount of haemoglobin A
- Raised levels of haemoglobin F
- Evidence that both parents have thalassaemia minor

Beta-thalassaemia minor (heterozygotes)
- Mild anaemia
- Microcytic hypochromic erythrocytes (not iron-deficient)
- Some target cells
- Punctate basophilia
- Raised haemoglobin A2 fraction

23.42 Anaemia in old age

- Mean haemoglobin: falls with age in both sexes but remains well within the reference range. When a low haemoglobin does occur, it is generally due to disease.
- Anaemia can never be considered ‘normal’ in old age.
- Symptoms: may be subtle and insidious. Cardiovascular features such as dyspnoea and oedema, and cerebral features such as dizziness and apathy, tend to predominate.
- Ferritin: if lower than 45 \(\mu g/L\) in older people, is highly predictive of iron deficiency. Conversely, ferritin may be raised by chronic disease and so a normal ferritin does not exclude iron deficiency.
- Serum iron and transferrin: fall with age because of the prevalence of other disorders, and are not reliable indicators of deficiency.
- Most common cause of iron deficiency: gastrointestinal blood loss.
- Most common cause of vitamin B12 deficiency: pernicious anaemia, as the prevalence of chronic atrophic gastritis rises in old age.
- Neuropsychiatric symptoms associated with vitamin B12 deficiency: well-established association but a causal relationship has not been clearly shown. Dementia associated with vitamin B12 deficiency in the absence of haematological abnormalities is rare.
- Anaemia of chronic disease: frequent in old age because of the rising prevalence of diseases that inhibit iron transport.

analysis sufficiently early in pregnancy to allow termination. This examination is appropriate only if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

23.43 Alpha-thalassaemia

Reduced or absent alpha-chain synthesis is common in South-east Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.
- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

Haematological malignancies

Haematological malignancies arise when the processes controlling proliferation or apoptosis are corrupted in blood cells because of acquired mutations in key regulatory genes. If mature differentiated cells are involved, the cells will have a low growth fraction and produce indolent neoplasms, such as the low-grade lymphomas or chronic leukemias, when patients have an expected survival of many years. In contrast, if more primitive stem or progenitor cells are involved, the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive, life-threatening illnesses such as the acute leukemias or high-grade lymphomas. Involvement of pluripotent stem cells produces the most aggressive acute leukemias. In general, haematological neoplasms are diseases of elderly patients, the exceptions being acute lymphoblastic leukaemia, which predominantly affects children, and Hodgkin lymphoma, which affects people aged 20–40 years. Management of young patients with haematological malignancy is particularly challenging (Box 23.43).

Leukaemias

Leukaemias are malignant disorders of the haematopoietic stem cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days to weeks to many years, depending on the type.

Epidemiology and aetiology

The incidence of leukaemia of all types in the population is approximately 10/100,000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 3:2 in acute leukaemia, 2:1 in chronic lymphocytic leukaemia and 1.3:1 in chronic myeloid leukaemia. Geographical variation in incidence does occur, the most striking being the ratio of chronic lymphocytic leukaemia in Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak of incidence in children aged 1–5 years. All forms of acute myeloid leukaemia
Terminology and classification

Leukaemias are traditionally classified into four main groups:

- Acute lymphoblastic leukaemia (ALL)
- Acute myeloid leukaemia (AML)
- Chronic lymphocytic leukaemia (CLL)
- Chronic myeloid leukaemia (CML)

In acute leukaemia, there is proliferation of primitive stem cells, with limited accompanying differentiation, leading to an accumulation of blasts, predominantly in the bone marrow, which causes bone marrow failure. In chronic leukaemia, the malignant clone is able to differentiate, resulting in an accumulation of more mature cells. Lymphocytic and lymphoblastic cells are those derived from the lymphoid stem cell (B cells and T cells).
the count is below $100 \times 10^9/L$. Severe thrombocytopenia is usual but not invariable. Frequently, blast cells are seen in the blood film but sometimes the blast cells may be infrequent or absent. A bone marrow examination will confirm the diagnosis. The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells in varying degrees (but more than 20% of the cells) (Fig. 23.23). The presence of Auer rods in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia. Classification and prognosis are determined by immunophenotyping and chromosome and molecular analysis, as shown in Figure 23.24.

**Management**

The first decision must be whether or not to give specific treatment to attempt to achieve remission. This is generally aggressive, has numerous side-effects, and may not be appropriate for the very elderly or patients with serious comorbidities (Chs 32 and 33). In these patients, supportive treatment can effect considerable improvement in well-being. Low-intensity chemotherapy, such as low-dose cytosine arabinoside or, recently, azacitidine, is frequently used in elderly and more frail patients but only induces remission in less than 20% of patients.

**Specific therapy**

Ideally, whenever possible, patients with acute leukaemia should be treated within a clinical trial. If a decision to embark on specific therapy has been taken, the patient should be prepared as recommended in Box 23.46. It is unwise to attempt aggressive management of acute leukaemia unless adequate services are available for the provision of supportive therapy.

The aim of treatment is to destroy the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of the haematopoietic tissues will occur. There are three phases:

- **Remission induction.** In this phase, a fraction of the tumour is destroyed by combination chemotherapy. The patient goes through a period of severe bone marrow hypoplasia lasting 3–4 weeks and requires intensive support and inpatient care from a specially trained multidisciplinary team. The aim is to achieve remission, a state in which the blood counts return to normal and the marrow blast count is less than 5%. Quality of life is highly dependent on achieving remission.

- **Remission consolidation.** If remission has been achieved, residual disease is attacked by therapy during the consolidation phase. This consists of a number of courses of chemotherapy, again resulting in periods of marrow hypoplasia. In poor-prognosis leukaemia, this may include allogeneic HSCT.

- **Remission maintenance.** If the patient is still in remission after the consolidation phase for ALL, a period of maintenance therapy is given, with the individual as an outpatient and treatment consisting of a repeating cycle of drug administration. This may extend for up to 3 years if relapse does not occur.

**Box 23.46 Preparation for specific therapy in acute leukaemia**

- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Anaemia corrected by red cell concentrate transfusion
- Thrombocytopenic bleeding controlled by platelet transfusions
- If possible, central venous catheter (e.g. Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy, fluids, blood products and other supportive drugs
- Tumour lysis risk assessed and prevention started: fluids with allopurinol or rasburicase
- Therapeutic regimen carefully explained to the patient and informed consent obtained
- Consideration of entry into clinical trial
In patients with ALL, it is necessary to give prophylactic treatment to the central nervous system, as this is a sanctuary site where standard therapy does not penetrate. This usually consists of a combination of cranial irradiation, intrathecal chemotherapy and high-dose methotrexate, which crosses the blood–brain barrier. Thereafter, specific therapy is discontinued and the patient observed.

The detail of the schedules for these treatments can be found in specialist texts. The drugs most commonly employed are listed in Box 23.47. Generally, if a patient fails to go into remission, alternative drug combinations may be tried, but the outlook is poor unless remission can be achieved. Disease that relapses during treatment or soon after the end of treatment carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective.

In some patients, alternative palliative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation. Drugs used for this purpose include hydroxycarbamide and mercaptopurine. The aim is to reduce the blast count without inducing bone marrow failure.

Supportive therapy

Aggressive and potentially curative therapy, which involves periods of severe bone marrow failure, would not be possible without appropriate supportive care. The following problems commonly arise.

Anæmia Anaemia is treated with red cell concentrate transfusions.

Bleeding Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Recent trials have confirmed that in acute leukaemia prophylactic platelet transfusion should be given to maintain the platelet count above 10 × 10^9/L. Coagulation abnormalities occur and need accurate diagnosis and treatment (p. 971).

Infection Fever (>38°C) lasting over 1 hour in a neutropenic patient indicates possible sepsis (see also p. 218). Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given according to local bacteriological resistance patterns, such as with a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam) or a single-agent beta-lactam (e.g. meropenem). The organisms most commonly associated with severe neutropenic sepsis are Gram-positive bacteria, such as Staphylococcus aureus and Staphylococcus epidermidis, which are present on the skin and gain entry via cannulae and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as *Escherichia coli*, *Pseudomonas* and *Klebsiella* spp. are likely to cause rapid clinical deterioration and must be covered with initially empirical antibiotic therapy. Gram-positive infection may require vancomycin or teicoplanin therapy. If fever has not resolved after 3–5 days and there is evidence of severe infection or positive blood cultures, empirical antifungal treatment (e.g. a liposomal amphotericin B preparation, voriconazole or caspofungin) is added.

Patients with ALL are susceptible to infection with *Pneumocystis jirovecii* (p. 318), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis may require induced sputum, bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal *Candida* infection is common. Fluconazole is effective for the treatment of local infection and for prophylaxis against systemic candidaemia. *Prophylaxis* against systemic fungal infections, including *Aspergillus*, is usually practised during high-risk intensive chemotherapy. This is often used along with sensitive markers of early fungal infection to guide treatment initiation (a “pre-emptive approach”).

For systemic fungal infection with *Candida* or aspergillosis, intravenous liposomal amphotericin, caspofungin or voriconazole is required for at least 3 weeks. In systemic *Candida* infection intravenous catheters should be removed.

Reactivation of herpes simplex infection (p. 247) occurs frequently around the lips and nose during ablative therapy for acute leukaemia, and is treated with aciclovir. This may also be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chickenpox or, after reactivation, as shingles (p. 239) should be treated in the early stage with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable but may contribute to staff awareness of careful reverse barrier nursing practice. The isolation can be psychologically stressful for the patient.

Metabolic problems Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic and diarrhoea is common as a consequence of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy...
(tumour lysis syndrome; p. 1328) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may lead to renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome, prophylactic rasburicase (a recombinant urate oxidase enzyme) is used. Occasionally, dialysis may be required.

**Psychological problems** Psychological support is a key aspect of care. Patients should be kept informed, and their questions answered and fears allayed as far as possible. A multidisciplinary approach to patient care involves input from many services, including psychology. Key members of the team include haematology specialist nurses, who are often the central point of contact for patients and families throughout the illness.

**Haematopoietic stem cell transplantation**

This is described on page 936. In patients with high-risk acute leukaemia, allogeneic HSCT can improve 5-year survival from 20% to around 50%. Reduced-intensity conditioning has allowed HSCT to be delivered to a higher proportion of patients with acute leukaemias, up to the age of about 65 years.

**Prognosis**

Without treatment, the median survival of patients with acute leukaemia is about 5 weeks. This may be extended to a number of months with supportive treatment. Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 23.48 shows the survival in ALL and AML and the influence of prognostic features. The level of detectable leukaemia cells, called minimal residual disease (MRD), measured after induction therapy in ALL by sensitive laboratory techniques, has been shown to be a powerful prognostic tool that is now used routinely to direct subsequent consolidation therapy.

Advances in treatment have led to steady improvement in survival from leukaemia. They include the introduction of drugs such as all-trans retinoic acid (ATRA) and arsenic trioxide (ATO) in acute promyelocytic leukaemia, which has greatly reduced induction deaths from bleeding in this good-risk leukaemia. A chemotherapy-free schedule of ATRA and ATO has recently produced cure rates of 90% in patients with low-risk acute promyelocytic leukaemia. Current trials aim to improve survival, especially in standard and poor-risk disease, with strategies that include better use of allogeneic HSCT and targeted therapies such as anti-CD33 monoclonal antibodies (Mylotarg) and FLT3 inhibitors. FLT3 is a cytokine receptor often expressed on AML blast cells and whose expression is associated with a poorer prognosis.

### Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is a myeloproliferative stem cell disorder resulting in proliferation of all haematopoietic lineages but manifesting predominantly in the granulocytic series. Maturation of cells proceeds fairly normally. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years.

The defining characteristic of CML is the chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the breakpoint cluster region (BCR). The fragment from chromosome 9 that joins the BCR carries the abl oncogene, which forms a fusion gene with the remains of the BCR. This BCR ABL fusion gene codes for a 210 kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene (p. 1318), influencing cellular proliferation, differentiation and survival. In some patients in whom conventional chromosomal analysis does not detect a Ph chromosome, the BCR ABL gene product is detectable by molecular techniques.

**Natural history**

The disease has three phases:

- **A chronic phase**, in which the disease is responsive to treatment and is easily controlled, which used to last 3–5 years. With the introduction of imatinib therapy, this phase has been prolonged to encompass a normal life expectancy in many patients.
- **An accelerated phase** (not always seen), in which disease control becomes more difficult.
- **Blast crisis**, in which the disease transforms into an acute leukaemia, either myeloblastic (70%) or lymphoblastic (30%), which is relatively refractory to treatment. This is the cause of death in the majority of patients; survival is therefore dictated by the timing of blast crisis, which cannot be predicted. Prior to imatinib therapy (see below), approximately 10% of patients per year would transform. In those treated with imatinib for up to 10 years, only between 0.5 and 2.5% have transformed each year.

**Clinical features**

Symptoms at presentation may include lethargy, weight loss, abdominal discomfort, gut and sweating, but about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10%, the enlargement is massive, extending to over 15 cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual.
Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to 600×10^9/L. In about one-third of patients, there is a very high platelet count, sometimes as high as 2000×10^9/L. In the blood film, the full range of granulocyte precursors, from myeloblasts to mature neutrophils, is seen but the predominant cells are neutrophils and myelocytes (see Fig. 23.3). Myeloblasts usually constitute less than 10% of all white cells. There is often an absolute increase in eosinophils and basophils, and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cell increases. Blast transformation is characterised by a dramatic increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophila tends to increase as the disease progresses.

Bone marrow should be obtained to confirm the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, and RNA analysis to demonstrate the presence of the BCR ABL gene product. Blood LDH levels are elevated and the uric acid level may be high due to increased cell breakdown.

Management

Chronic phase

There are now five available tyrosine kinase inhibitors (TKIs) for the treatment of CML (Box 23.49). These specifically inhibit BCR ABL tyrosine kinase activity. Imatinib, nilotinib and dasatinib are recommended as first-line therapy in chronic phase CML; they usually normalise the blood count within a month and within 3–6 months produce complete cytogenetic response (disappearance of the Ph chromosome) in some 90% of patients. A sample of bone marrow is taken at 6 months to confirm complete cytogenetic response, and patients are subsequently monitored by 3-monthly real-time quantitative polymerase chain reaction (PCR) for BCR ABL mRNA transcripts in blood. The aim is to reduce the BCR ABL transcript levels by 3–5 logs from baseline and this is called major molecular response (MR3–MR5). A proportion of patients achieve a complete molecular response where the transcripts are not detectable by PCR. It may be possible for patients with a complete or major molecular response to stop TKI therapy and this is being investigated in clinical trials. For those failing to respond or who lose their response and progress on first-line therapy, options include switching to a different TKI (Box 23.49). Some patients develop detectable mutations in the BCR ABL gene, which renders them resistant to one or more of the TKIs. The T315I mutation has been particularly problematic, as this provides wide-ranging resistance. The third-generation TKI ponatinib is effective, however. Allogeneic HSCT (p. 937) is now reserved for patients who fail TKI therapy. Hydroxyurea and interferon were previously used for control of disease. Hydroxyurea is still useful in palliative situations and interferon is used in women planning pregnancy.

Accelerated phase and blast crisis

Management is more difficult. For patients in accelerated phase, TKI therapy is indicated, most commonly with nilotinib or dasatinib. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 23.49) is better if disease is lymphoblastic than if myeloblastic. Second- or third-generation TKIs such as dasatinib are used in combination with chemotherapy to try and achieve remission. In younger and fitter patients an allogeneic HSCT is appropriate therapy if a return to chronic phase is achieved. Hydroxyurea can be an effective single agent and low-dose cytarabine can also be used palliatively in older patients.

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common variety of leukaemia, accounting for 30% of cases. The male-to-female ratio is 2:1 and the median age at presentation is 65–70 years. In this disease, B lymphocytes, which would normally respond to antigens by transformation and antibody formation, fail to do so. An ever-increasing mass of immuno-incompetent cells accumulates, to the detriment of immune function and normal bone marrow haematopoiesis.

Clinical features

The onset is usually insidious. Indeed, in around 70% of patients, the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss; these more often occur later in the course of the disease.

Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis (>5×10^9/L) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B-cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T-cell antigen CD5. On flow cytometry, some people are shown to have circulating CLL cells at a level less than 5×10^9/L. This is known as monoclonal B lymphocytosis of uncertain significance.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test, as autoimmune haemolytic anaemia may occur (p. 949). Serum immunoglobulin levels should be estimated to establish the degree of hypogammaglobulinaemia, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for prognosis (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. The main prognostic factor is...
For patients who are under 70 years, fit and the age and fitness of the patient and the rapidly increasing lymphocyte count, autoimmune haemolytic systemic symptoms such as weight loss or night sweats, a failure, massive or progressive lymphadenopathy or splenomegaly, disease, as the diagnosis of leukaemia inevitably causes anxiety. About CLL and be reassured about the indolent nature of the older patients. The patient should be offered clear information unless progression occurs. Life expectancy is usually normal in Management

Stage of disease (Box 23.50); however, loss of chromosome 17p or mutation in the TP53 gene, which resides at this genetic locus, is a powerful prognostic marker and predictor of response to therapy. A mutation in TP53 is present in <10% of patients at presentation but rises to 30% of cases at relapse. This test should be performed in all patients prior to the initiation of therapy.

Management

No specific treatment is required for most clinical stage A patients, unless progression occurs. Life expectancy is usually normal in older patients. The patient should be offered clear information about CLL and be reassured about the indolent nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety.

Treatment is required only if there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count, autoimmune haemolytic anaemia or thrombocytopenia. Initial treatment for those requiring treatment (progressive stage A and stages B and C) is based on the age and fitness of the patient and the TP53 mutation status. For patients who are under 70 years, fit and TP53 mutation-negative, fludarabine in combination with the alkylating agent cyclophosphamide and the anti-CD20 monoclonal antibody rituximab (FCR) is standard care. For older, less fit patients, rituximab is combined with gentler chemotherapy: bendamustine and idelalisib are licensed for relapsed CLL but crucially are PI3 kinase, both components of the BCR pathway. Ibrutinib inhibit this pathway are now available and show great promise.

Blast cells may be increased marrow is hypercellular, with dysplastic changes in at least 10% of neutrophils with nuclear hyper- or hyposegmentation. The bone blood cells, including macrocytic red cells and hypogranular platelets and red cells. Chronic myeloid leukaemia (CML) is a clonal haematopoietic disorder characterised by cytopenias and abnormal-looking (dysplastic) bone marrow failure or autoimmune cytopenias may respond to glucocorticoid treatment.

Supportive care is increasingly required in progressive disease, such as transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections and, for some patients with hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymphadenopathy that is causing discomfort or local obstruction, and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism, and can relieve massive splenomegaly.

Prognosis

The majority of clinical stage A patients have a normal life expectancy but patients with advanced CLL are more likely to die from their disease or infectious complications. Survival is influenced by prognostic features of the leukaemia, particularly TP53 mutation status, and whether patients can tolerate and respond to fludarabine-based treatment. In those able to be treated with chemotherapy and rituximab, 90% are alive 4 years later. Rarely, CLL transforms to an aggressive high-grade lymphoma, called Richter’s transformation.

Prolymphocytic leukaemia

Prolymphocytic leukaemia (PLL) is a variant of chronic lymphocytic leukaemia found mainly in males over the age of 60 years; 25% of cases are of the T-cell variety. There is typically massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often in excess of 400 x 10⁹/L. The characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis is very poor. Leukapharesis, splenectomy and chemotherapy may be tried. The anti-CD52 antibody alemtuzumab, when given intravenously, has produced responses in some 90% of patients with T-PLL.

Hairy cell leukaemia

This is a rare chronic B-cell lymphoproliferative disorder. The male-to-female ratio is 6:1 and the median age at diagnosis is 50 years. Presenting symptoms are general ill health and recurrent infections. Splenomegaly occurs in 90% but lymph node enlargement is unusual.

Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B-lymphocyte immunotype but they also characteristically express CD25 and CD103. Recently, all patients with hairy cell leukaemia have been found to have a mutation in the BRAF gene.

Over recent years, a number of treatments, including cladribine and deoxycoformycin, have been shown to produce long-lasting remissions.

Myelodysplastic syndromes

Myelodysplastic syndromes (MDSs) constitute a group of clonal haematopoietic disorders with the common features of ineffective blood cell production and a tendency to progress to AML. As such, they are pre-leukaemic and represent genetic steps in the development of leukaemia. These genetic abnormalities have been identified and are present as a manifestation of clonal haematopoiesis in about 3% of patients over the age of 80, at a time when their blood counts are normal (clonal haematopoiesis of indeterminate potential, CHIP). MDS presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), usually in older people (median age at diagnosis is 73 years). The overall incidence is 4/100,000 in the population, rising to more than 30/100,000 in the over-seventies. The blood film is characterised by cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular, with dysplastic changes in at least 10% of cells of one or more cell lines. Blast cells may be increased but do not reach the 20% level that indicates acute leukaemia. Chromosome analysis frequently reveals abnormalities, particularly
of chromosome 5 or 7. The WHO classification of MDS is shown in Box 23.51.

**Prognosis**

The natural history of MDS is progressive worsening of dysplasia leading to fatal bone marrow failure or progression to AML in 30% of cases. The time to progression varies (from months to years) with the subtype of MDS, being slowest in MDS with ring sideroblasts and single-lineage dysplasia and most rapid in MDS with excess blasts. The revised International Prognostic Scoring System (IPSS-R) predicts clinical outcome based on karyotype and cytopenias in blood, as well as percentage of bone marrow blasts (Box 23.52). There are five prognostic groups. The median survival for low-risk patients (IPSS-R very low and low) is 5–9 years, that for the intermediate group is 3 years and that for high-risk patients (IPSS-R high and very high) is 1–1.5 years.

**Management**

For the vast majority of patients who are elderly, the disease is incurable, and supportive care with red cell and platelet transfusions is the mainstay of treatment. A trial of erythropoiesis-stimulating agents (ESA) and granulocyte–colony-stimulating factor (G-CSF) is recommended in some patients with low-risk MDS (IPSS-R very low, low and intermediate) to improve haemoglobin or neutrophil counts. A rare subtype called MDS with isolated del(5q) responds well to the immunomodulatory drug lenalidomide, with two-thirds of anaemic patients becoming transfusion-independent for up to 2 years. Allogeneic stem cell transplantation may afford a cure in patients with a good performance status and is considered in high-risk patients (IPSS-R high and very high) and some low-risk patients. More recently, the hypomethylating agent azacytidine has improved survival by a median of 9 months for high-risk patients, and in the UK is a recommended standard of care for those not eligible for transplantation.

**Lymphomas**

These neoplasms arise from lymphoid tissues, and are diagnosed from the pathological findings on biopsy as Hodgkin or non-Hodgkin lymphoma. The majority are of B-cell origin. Non-Hodgkin lymphomas are classified as low- or high-grade tumours on the basis of their proliferation rate. The normal architecture of the lymph node is outlined in Figure 23.25.

- **High-grade tumours** divide rapidly, are typically present for a matter of weeks before diagnosis, and may be life-threatening with frequent risk of extranodal involvement.
- **Low-grade tumours** divide slowly, may be present for many months before diagnosis, and typically behave in an indolent fashion.

**Hodgkin lymphoma**

The histological hallmark of Hodgkin lymphoma (HL) is the presence of Reed–Sternberg cells: large, malignant lymphoid cells of B-cell origin (Fig. 23.26). They are often present only in small numbers but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and eosinophils. The epidemiology of HL is shown in Box 23.53 and its histological WHO classification in Box 23.54.

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. It has biological features, such as CD20-positive Hodgkin cells, and clinical features that make it more akin to a low-grade B-cell non-Hodgkin lymphoma. Classical HL is divided into four histological subtypes from the appearance of the

*The IPSS-R is based on three prognostic factors: the blast percentage in bone marrow, karyotype, and number and degree of blood cytopenias. A score is derived from which patients can be stratified into five risk categories for survival and leukemic transformation.*

---

**Fig. 23.25 Schema of lymph node architecture.** Different lymphocyte populations reside in different areas of the node: B cells in the follicles, T cells in the paracortex and plasma cells in the medulla. B cells are selected for antigen in the follicle centre. Errors during this process result in B-cell lymphomas, which are by far the most common type.
but may cause dry cough and some breathlessness. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present but does not always indicate disease in those organs. Spread is contiguous from one node to the next, and extranodal disease, such as bone, brain or skin involvement, is rare.

**Investigations**

Treatment of HL depends on the stage at presentation; investigations therefore aim not only to diagnose lymphoma but also to determine the extent of disease (Box 23.55).

- **FBC** may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor. An eosinophilia or a neutrophilia may be present.
- **ESR** may be raised.
- **Renal function tests** are required to ensure function is normal prior to treatment.
- **Liver function** may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatis.
- **LDH measurements** showing raised levels are an adverse prognostic factor.
- **Chest X-ray** may show a mediastinal mass.
- **CT scan** of chest, abdomen and pelvis permits staging. Bulky disease (> 10 cm in a single node mass) is an adverse prognostic feature.
- **Positron emission tomography (PET) scanning** identifies nodes involved with HL, which are 18F-fluorodeoxyglucose (FDG)-avid, and this allows more accurate staging and monitoring of response (Fig. 23.27).
- **Lymph node biopsy** may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 23.28).

**Management**

Clinical trials have shown that patients with early-stage disease (stages IA and IIA) have better outcomes if limited cycles of chemotherapy are combined with radiotherapy, rather than using radiotherapy alone.
rate and decades of life ahead of them. Recent randomised trial data from the UK RAPID study have suggested that early-stage patients without bulk disease who have a negative PET scan after three cycles of ABVD can safely omit radiotherapy. Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a screening programme. Patients continuing to smoke after lung irradiation are at particular risk of lung cancer.

ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. The incidence of infertility and secondary myelodysplasia/AML is low with this regimen.

Patients with advanced-stage disease are most commonly managed with chemotherapy alone. Standard treatment in the UK is 6–8 cycles of ABVD, followed by an assessment of response. The recent UK RATHL trial has confirmed previous data showing that achieving a PET-negative response after two cycles of ABVD (interim PET-2 response) predicts a very good outcome from continuing with up to six cycles of ABVD. Indeed, the same outcome can be achieved by omitting the bleomycin from the last four cycles and using just AVD, thus reducing the risk of lung toxicity. Patients who are PET-positive after two cycles, however, have a very high relapse risk if they continue with ABVD, only 13% being relapse-free at 2 years. The RATHL and other studies have demonstrated that changing to a more intensive regimen, BEACOPP (bleomycin, etoposide, adriamycin, cyclophosphamide, vincristine (oncovin), procarbazine, prednisolone), in these patients improves the relapse-free survival to approximately 65%.

Patients with relapsed disease that responds to salvage chemotherapy and ideally becomes PET-negative should be considered for autologous stem cell transplantation (p. 937). Those with resistant disease might benefit from an allogeneic donor.

The ABVD regimen (doxorubicin, bleomycin, vinblastine and dacarbazine) is widely used in the UK. Standard therapy for early-stage patients without additional risk factors, such as bulk disease or high ESR, is two cycles of ABVD combined with 20 Gy radiotherapy to the involved sites of disease. Standard therapy for early-stage patients with additional risk factors is four cycles of ABVD combined with 30 Gy radiotherapy. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues and new planning techniques continue to improve targeting of radiotherapy. Nevertheless, the long-term risks of second cancers and heart and lung disease within the radiation fields remain a concern, especially for young people with a high cure
stem cell transplant. Brentuximab vedotin is an antibody–drug conjugate directed against CD30 on the Reed–Sternberg cell surface. This antibody delivers the antimitotic toxin monomethyl auristatin E to the Hodgkin cells and, as a single agent, can produce good responses in patients who have failed, or are not suitable for, an autologous transplant and can be a “bridge” to an allogeneic transplant.

**Prognosis**

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy followed by involved field radiotherapy, and the great majority are cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group. Omitting radiotherapy in the majority of PET-negative patients is one major step forward in this regard.

Historically, between 50 and 70% of those with advanced-stage HL were cured. The Hasenclever index (Box 23.56) can be helpful in assigning approximate chances of cure when discussing treatment plans with patients. More recent data using the PET scanner to direct therapy suggests that long-term survival is improving to beyond 80%. Patients who fail to respond to initial chemotherapy or relapse within a year of initial therapy have a poor prognosis but some may achieve long-term survival after chemotherapy or relapse within a year of initial therapy have a poor prognosis but some may achieve long-term survival.

Patients relapsing after 1 year may obtain long-term survival with further chemotherapy alone, but fit patients may proceed to autologous HSCT. Brentuximab vedotin is an antibody–drug conjugate directed against CD30 on the Reed–Sternberg cell surface. This antibody delivers the antimitotic toxin monomethyl auristatin E to the Hodgkin cells and, as a single agent, can produce good responses in patients who have failed, or are not suitable for, an autologous transplant and can be a “bridge” to an allogeneic transplant.

**Non-Hodgkin lymphoma**

Non-Hodgkin lymphoma (NHL) represents a monoclonal proliferation of lymphoid cells of B-cell (90%) or T-cell (10%) origin. The incidence of these tumours increases with age, to 62.8/million population per annum at age 75 years, and the overall rate is increasing at about 3% per year.

The epidemiology of NHL is shown in Box 23.57. Previous classifications were based principally on histological appearances. The current WHO classification stratifies according to cell lineage (T or B cells) and incorporates clinical features, histology, chromosomal abnormalities and concepts related to the biology of the lymphoma. Clinically, the most important factor is grade, which is a reflection of proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months or even years before presentation, runs an indolent course, but is not curable by conventional therapy. Of all cases of NHL in the developed world, over two-thirds are either diffuse large B-cell NHL (high-grade) or follicular NHL (low-grade) (Fig. 23.29). Other forms of NHL, including Burkitt lymphoma, mantle cell lymphoma, mucosa-associated lymphoid tissue (MALT) lymphomas and T-cell lymphomas, are less common.

**Clinical features**

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement (Fig. 23.30), which may be associated with systemic upset: weight loss, sweats, fever and itching. Hepatosplenomegaly may be present. Sites of extranodal involvement include the bone marrow, gut, thyroid, lung, skin, testis, brain and, more rarely, bone. Bone marrow involvement is more common in low-grade (50–60%) than high-grade (10%) disease. Compression syndromes may occur, including gut obstruction, ascites, superior vena cava obstruction and spinal cord compression.

The same staging system (see Box 23.55) is used for both HL and NHL, but NHL is more likely to be stage III or IV at presentation.

**Investigations**

These are as for HL, but in addition the following should be performed:

- **Bone marrow aspiration and trephine** to identify bone marrow involvement.
- **Immunophenotyping of surface antigens to distinguish T-cell from B-cell tumours**. This may be done on blood, marrow or nodal material.
Haematological malignancies

Fig. 23.29 Histology of non-Hodgkin lymphoma. A (Low-grade) follicular or nodular pattern. B (High-grade) diffuse pattern.

- Cytogenetic analysis to detect chromosomal translocations and molecular testing for T-cell receptor or immunoglobulin gene rearrangements.
- Immunoglobulin determination. Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- Measurement of uric acid levels. Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started.
- HIV testing. HIV is a risk factor for some lymphomas and affects treatment decisions.
- Hepatitis B and C testing. This should be done prior to therapy with rituximab.

Management

Low-grade NHL

The majority of patients (80%) present with advanced stage disease and will run a relapsing and remitting course over several years. Asymptomatic patients may not require therapy and are managed by ‘watching and waiting’. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement, bone marrow failure or compression syndromes. In follicular lymphoma, the options are:

- Radiotherapy. This can be used for localised stage I disease, which is rare.
- Chemotherapy. Most patients will respond to oral therapy with chlorambucil, which is well tolerated but not curative. More intensive intravenous chemotherapy in younger patients produces better quality of life but no survival benefit.
- Monoclonal antibody therapy. Humanised monoclonal antibodies (‘biological therapy’; p. 960) can be used to target surface antigens on tumour cells and to induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone, and acts synergistically when given with chemotherapy. Rituximab (R) in combination with cyclophosphamide, vincristine and prednisolone (R-CVP), cyclophosphamide, doxorubicin, vincristine, prednisolone (R-CHOP) or bendamustine (R-bendamustine) is commonly used as first-line therapy. Randomised trials have also confirmed that 2 years of maintenance therapy with single-agent rituximab, following achievement of first or second response, delays relapse and the time to next treatment. As yet, however, rituximab maintenance has not shown a survival benefit. New and more potent monoclonal antibodies are also in development and trials of obinutuzumab (p. 960) have been completed.
- Kinase inhibitors. Idelalisib is approved for relapsed follicular lymphoma and ibrutinib (p. 960) is approved for relapsed mantle cell lymphoma, a poor-prognosis lymphoma with low-grade histology but aggressive clinical behaviour. These targeted therapies are likely to become more widely used in low-grade lymphomas in the near future.
- Transplantation. High-dose chemotherapy and autologous HSCT can produce long remissions in patients with relapsed disease. Decisions on the timing of such treatment are complex in the context of rituximab maintenance and newer targeted therapies. However, younger patients with short first or second remissions or who relapse during rituximab maintenance should be considered.
High-grade NHL

Patients with diffuse large B-cell NHL need treatment at initial presentation:

- **Chemotherapy.** The majority (>90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin, vincristine and prednisolone).
- **Monoclonal antibody therapy.** When combined with CHOP chemotherapy, rituximab (R) increases the complete response rates and improves overall survival. R-CHOP is currently recommended as first-line therapy for those with stage II or higher diffuse large B-cell lymphoma.
- **Radiotherapy.** Stage I patients without bulky disease are treated with four cycles of CHOP or R-CHOP, followed by involved site radiotherapy. Radiotherapy is also indicated for a residual localised site of bulk disease after chemotherapy, and for spinal cord and other compression syndromes.
- **HSCT.** Autologous HSCT (p. 937) benefits patients with relapsed disease that is sensitive to salvage immunochemotherapy. As with HL, achieving PET negativity prior to autologous transplantation is desirable.

**Prognosis**

Low-grade NHL runs an indolent remitting and relapsing course, with an overall median survival of 12 years. Transformation to a high-grade NHL occurs in 3% per annum and is associated with poor survival.

In diffuse large B-cell NHL treated with R-CHOP, some 75% of patients overall respond initially to therapy and 50% will have disease-free survival at 5 years. The prognosis for patients with NHL is further refined according to the international prognostic index (IPI). For high-grade NHL, 5-year survival ranges from over 75% in those with low-risk scores (age <60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Relapse is associated with a poor response to further chemotherapy (<10% 5-year survival), but in patients under 65 years HSCT improves survival.

**Waldenström macroglobulinaemia**

This is a low-grade lymphoplasmacytic lymphoma associated with an IgM paraprotein, causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in the elderly and more commonly affects males.

Patients classically present with features of hyperviscosity, such as nosebleeds, bruising, delirium and visual disturbance. However, presentation may be with anaemia, systemic symptoms, splenomegaly or lymphadenopathy, or may be asymptomatic, with an IgM paraprotein detected on routine screening. Patients are found on investigation to have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells, plasma cells and sometimes prominent mast cells. A high proportion of patients have a mutation in the MYD88 gene.

**Management**

If patients show symptoms of hyperviscosity and anaemia, plasmapheresis is required to remove IgM and make blood transfusion possible. Chemotherapy with alkylating agents, such as chlorambucil, has been the mainstay of treatment, controlling disease in over 50%. Fludarabine may be more effective in this disease but has more side-effects. Rituximab in combination with chemotherapy is most commonly used; ibrutinib is very effective and has recently been licensed for use. Rituximab alone can cause a rapid release of IgM and increase in viscosity. The median survival is 5 years.

**Multiple myeloma**

This is a malignant proliferation of plasma cells. Normal plasma cells are derived from B cells and produce immunoglobulins that contain heavy and light chains. Normal immunoglobulins are polyclonal, which means that a variety of heavy chains are produced and each may be of kappa or lambda light chain type (p. 68). In myeloma, plasma cells produce immunoglobulin of a single heavy and light chain, a monoclonal protein commonly referred to as a paraprotein. In most cases an excess of light chain is produced, and in some cases only light chain is produced;
Haematological malignancies

The clinical features are demonstrated in Figure 23.31.

Diagnosis of myeloma requires two of the following criteria to be fulfilled:

- increased malignant plasma cells in the bone marrow
- serum and/or urinary M-protein
- skeletal lytic lesions.

Bone marrow aspiration, plasma and urine electrophoresis, and a skeletal survey are thus required. Normal immunoglobulin levels, i.e. the absence of immunoparesis, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR but this is a non-specific test; only approximately 5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma.

**Management**

If patients are asymptomatic with no evidence of end-organ damage (e.g. to kidneys, bone marrow or bone), treatment may not be required. So-called asymptomatic myeloma should be monitored closely for the development of end-organ damage.

**Immediate support**

- High fluid intake to treat renal impairment and hypercalcaemia (p. 661).
- Analgesia for bone pain.
• Plasmapheresis, if necessary, for hyperviscosity.

Chemotherapy with or without HSCT

Myeloma therapy has improved with the addition of novel agents, initially thalidomide and more recently the proteasome inhibitor bortezomib and the second-generation immunomodulatory drug lenalidomide. For first-line therapy in older patients, thalidomide combined with the alkylating agent melphalan and prednisolone (MPT) has increased the median overall survival to more than 4 years. Lenalidomide is approved first-line treatment for patients not eligible for transplantation and who are intolerant of, or unsuitable for, thalidomide. Thalidomide and lenalidomide both have anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. Both can cause somnolence, constipation, peripheral neuropathy and thrombosis, though lenalidomide has a better side-effect profile. It is vital that females of child-bearing age use adequate contraception, as thalidomide and lenalidomide are teratogenic. Treatment is administered until paraprotein levels have stopped falling. This is termed ‘plateau phase’ and can last for weeks or years.

In younger, fitter patients, standard treatment includes first-line therapies, such as cyclophosphamide, thalidomide and dexamethasone (CTD) or bortezomib (Velcade), thalidomide and dexamethasone (VTD) to maximum response, and then autologous HSCT, which improves quality of life and prolongs survival but does not cure myeloma. In all patients who have achieved maximal response, lenalidomide maintenance has been shown to prolong the response.

When myeloma progresses, treatment is given to induce a further plateau phase. In the UK, the proteasome inhibitor bortezomib and lenalidomide have been used as second- and third-line therapy, as appropriate. As they have been used more frequently in the first or second line with prognostic benefit, however, subsequent relapses are more difficult to treat. A second-generation proteasome inhibitor, carfilzomib, and the anti-CD38 antibody daratumumab show promise in relapsed/refractory disease. Responding patients may benefit from a second autologous HSCT.

Radiotherapy

This is effective for localised bone pain not responding to simple analgesia and for pathological fractures. It is also useful for the emergency treatment of spinal cord compression complicating extradural plasmacytomata.

Bisphosphonates

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone (p. 1047) and may cause apoptosis of malignant plasma cells. There is evidence that intravenous zolendronate in combination with anti-myeloma therapy confers a survival advantage over oral bisphosphonates. Osteonecrosis of the jaw may be associated with long-term use or poor oral hygiene and gum sepsis; regular dental review, including a check before starting therapy, is therefore important.

Prognosis

The international staging system (ISS) identifies poor prognostic features, including a high β2-microglobulin and low albumin at diagnosis (ISS stage 3, median survival 29 months). Those with a normal albumin and a low β2-microglobulin (ISS stage 1) have a median survival of 62 months. Increasingly, cytogenetic analysis is used to identify poor-risk patients, e.g. t(4;14), del(17p13), t(14;16), t(14;20), non-hyperdiploidy and gain(1q). Use of autologous HSCT and advances in drug therapy with the newer agents have increased survival. Over one-third of patients are now surviving for 5 years, compared with only one-quarter 10 years ago. The outlook may improve further with new drugs and combinations of treatments.

Aplastic anaemias

Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum. The disease is much more common in certain other parts of the world, e.g. east Asia. The basic problem is failure of the pluripotent stem cells because of an autoimmune attack, producing hypoplasia of the bone marrow with a pancytopenia in the blood. The diagnosis rests on exclusion of other causes of secondary aplastic anaemia (see below) and rare congenital causes, such as Fanconi’s anaemia.

Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly, infections. An FBC demonstrates pancytopenia, low reticulocytes and usually anaemia or bleeding, and less commonly, infections. An FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. Bone marrow aspiration and trephine reveal hypocellularity. The severity of aplastic anaemia is graded according to the Camitta criteria (Box 23.60).

23.59 Haematological malignancy in old age

- Median age: approximately 70 years for most haematological malignancies.
- Poor-risk biological features: adverse cytogenetics or the presence of a multidrug resistance phenotype are more frequent.
- Prognosis: increasing age is an independent adverse variable in acute leukaemia and aggressive lymphoma.
- Chemotherapy: may be less well tolerated. Older people are more likely to have antecedent cardiac, pulmonary or metabolic problems, tolerate systemic infection less well and metabolise cytotoxic drugs differently.
- Cure rates: similar to those in younger patients, in those who do tolerate treatment.
- Decision to treat: should be based on the individual’s biological status, the level of social support available, and the patient’s wishes and those of the immediate family, but not on chronological age alone.
